HONORARY MANAGING COMMITTEE

APPOINTED BY THE SECRETARY OF STATE FOR THE COLONIES

Chairman A. M. Wilson Rae, C.M.G. M.D.

(Deputy Chief Medical Officer Colonial Office)

Professor Patrick A. Buxton, C.M.G. M.A., M.R.C.S., L.R.C.P. D.T.M. & H., F.R.S.
(representing the Royal Society)

Lieut-General Sir James Bennett Haec, K.C.I.E., O.B.E., M.D., F.R.C.S.E., K.H.S.,
L.M.S. (retd.).

Sir Wilson Jameson, K.C.B., LL.D. M.D., F.R.C.P. K.H.F.
(representing the Ministry of Health)

Professor J. M. MacIntosh, M.D., F.R.C.P. D.P.H.

Sir Philip Manson-Bahr C.M.G. D.S.O. M.D. F.R.C.P. D.T.M. & H.

Sir Edward Mellanby O.B.E., K.C.S. M.D. Sc.D. F.R.C.P. F.R.S.
(representing the Medical Research Council)

H. R. A. Macerweather C.B.E., M.D., F.R.C.P. F.R.S.E.

Brigadier G. S. Parkinson, C.B.E., D.S.O. M.R.C.S. L.R.C.P. D.P.H., R.A.M.C. (retd.).

J. B. Siddons, C.M.G. M.A. *(of the Colonial Office)*

Secretary J. C. Bilton *(of the Colonial Office)*

STAFF OF THE BUREAU

Director Charles Wilcocks, M.D. M.R.C.P. D.T.M. & H.

Assistant Director H. J. O'D. Burke-Gaffney O.B.E., M.D.

1 *Historical*

The epidemic of *T. gambiense* sleeping sickness which occurred in Uganda in the early years of the present century gradually spread down both sides of Lake Victoria and invaded German East Africa (now Tanganyika Territory). In 1907, the Germans established sleeping sickness camps at Kigarama, on the west shore of Lake Victoria just south of the Uganda border, and at Shirati on the east side, near the Kenya border [*Sleeping Sickness Bulletin*, 1909, v 1, 243]. In 1908, cases of sleeping sickness were discovered on Ukerewe Island, at the south of the Lake, and on the Islands of Bumbire and Iroba near the eastern shore and on the mainland of Ihangiro opposite to them [*ibid*, 396]. On Lake Victoria the Germans recorded 1,405 cases, of sleeping sickness in 1908-9, and 27 cases in 1912-13 (MACLEAN, 1927).

By extensive bush clearing, particularly along the River Mori, south of Shirati [*Sleeping Sickness Bulletin*, 1912, v 4, 244], they appear to have eliminated the tsetse fly and stopped the southward spread of the disease. It was while working in the River Mori area that KLEINE (1909) discovered the cyclical transmission of *T. gambiense* by *Glossina palpalis*.

Lake Tanganyika—Sleeping sickness reached the western (Congo) shore of Lake Tanganyika about 1901 and soon reached the eastern (German) shore, where it quickly spread. The Germans remarked that numbers of Africans,

bearers of trypanosomes, came from the Belgian Congo to German territory in one caravan of sixteen, ten persons were found to be infected [*Sleeping Sickness Bulletin* 1909 v 1 398].

By 1907 the authorities had established a sleeping sickness camp at Nianza at the north end of the Lake and they recorded the disease as being present in the northern third of the Lake shore from Usumbura to the River Malagarasi [*ibid.*, 243]. In October 1908 1,517 patients were under treatment [*ibid.*, 396] but this number apparently included the Lake Victoria cases as well. Extensive clearings were undertaken, as in the Lake Victoria area.

By 1914 the Germans had had complete success in combating the disease in the Lake Victoria region, but they considered that the most widespread and most dangerous seat of infection was the Lake Tanganyika coast. The principal efforts of the Government were directed towards preventing the introduction of fresh cases, controlling native traffic, and clearing bush. No Africans from German East Africa were allowed to act as porters in the Belgian Congo [this *Bulletin*, 1914 v 3, 527].

It was while working at Nianza that TAUTZ in 1911 showed that *G. morsulus* could transmit trypanosomes cyclically [*Sleeping Sickness Bulletin* 1911 v 3 291], an observation shortly afterwards published independently by KINGDOM [*ibid.*, 391].

MACLEAN (1927) stated that in 1912-13 there were 3,303 cases under observation, but that most of these were from Ruanda-Urundi, now Belgian Mandated Territory (the northern part of Lake Tanganyika). He stated further that cases were found at the Malagarasi Delta by the Belgian authorities during their occupation of Kigoma and Western Ujiji between 1918 and 1921 but that no records were available and the numbers were not known.

South-Eastern Fly-Block.—In 1911 a focus of human trypanosomiasis was discovered on the upper reaches of the River Rovuma in the Songea District [*Sleeping Sickness Bulletin* 1912, v 4 202]. LAMBORN and HOWAT (1936) give a fuller account of this. They quote from an unpublished report by a German, Dr. Wolf (this is, possibly the Dr. Wolf cited to by Strynnyer, 1923) that early in 1910 an African was found ill with trypanosomiasis. He had come from his village at the junction of the upper Rovuma and Sasawaru (? Sasawaru) rivers. After this patient had been discovered, numerous cases of the same disease occurred along the route on which it was definitely ascertained, he had travelled. In 1911 a segregation camp was established at Sasawaru to deal with the outbreak, and between 1911 and 1913 seventy-two cases were isolated. From this area the disease spread northwards, and in 1917 it had reached the hinterland of Kilwa, having crossed the River Mbemkuru. TAUTZ and HUNER (quoted by SWYNNERTON 1923) stated that the foci of human trypanosomiasis behind Kilwa and Lindi and further south were confined to water-holes and the banks of rivers that were the halting places for Yao labourers passing from the southern infected foci to the Lindi-Kilwa plantations, and that cases did not occur in the surrounding country. TAUTZ in 1913 established that the disease in this area was due to *T. rhodesiense* [this *Bulletin* 1913 v 1 513].

It was in the Rovuma area in 1917 that TAUTZ and HUNER (1919) inoculated themselves and 129 Africans with six different strains of *T. brucei* derived from four naturally infected horses and two naturally infected mules, without being infected. This experiment was designed to show that *T. brucei* and *T. rhodesiense* were distinct species.

The Tsetse Flies Present

The large area of Tanganyika Territory which is infested with tsetse flies is shown on the accompanying map.

The distribution of tsetse flies and the spread of sleeping sickness in Tanganyika Territory

The western and eastern fly blocks are mainly occupied by *Isoperla* and *Phyllodactylus* (woodland carrying *Glossina morsitans* in which pockets of *Phyllodactylus* and *G. morsitans* occur). The northern fly blocks are *Acacia* and *G. morsitans* in isolated areas. In one area of Shinyanga *G. morsitans* is also present in the last two areas. *Phyllodactylus* occurs on the shores of Lake Victoria. Maclean (1927) reached the Lake shore in many places from the Malagasy delta and that it was not uncommon to find both these species at the spot. *Phyllodactylus* occurs from the Kenya border through Mbulu district to the west of Lake East. *G. morsitans* is present in the coastal belt on the west of the Territory while *G. morsitans* occurs just over the Kenyan

For the detailed distribution of the various species the reader should consult PORTS (1937) or the tsetse fly map in "The Atlas of the Tanganyika Territory (1942) issued by the Tanganyika Territory Department of Lands and Mines, Survey Division.

3. The Recent Outbreaks of Sleeping Sickness due to *T. rhodesiense*

In 1922, sleeping sickness of the *T. rhodesiense* type was identified in Maswa District and up to the end of 1946 a total of 23,965 cases of the disease have been diagnosed microscopically in the Territory. During epidemic periods many more people probably died undiagnosed. The yearly incidence of the cases in the various areas is shown in Appendix I (p. 16) and the spread of the disease over the Territory is illustrated in the map.

Maswa—At the end of February 1922, a large number of African deaths were reported from the Maswa fly-block and investigations by Maclean established the fact that the cause was sleeping sickness, the responsible trypanosome being *T. rhodesiense*. The people were emphatic that the village of Igombe on the western border of the Maswa fly-block, was an early focus of the disease, and they traced its passage thence from village to village, naming each until it came to their own neighbourhood (SWYNNEPORT 1923). Swynneport stated that it was always easy to trace a sequence between any case and preceding cases—going to see the sick, and taking the sick in, seem to have been the commonest sources of infection recognized by the local Africans. There was no indication of new and independent infections—every case appeared to be traceable to contact with sick persons in the presence of tsetse.

Thoma—There is constant foot traffic of Africans between Maswa and the hinterland tribes of Musoma District, and in the Ikoma area of Musoma District where it has become endemic, this disease was first diagnosed in the middle of 1925.

The Western Fly-Block.—The next outbreak of trypanosomiasis, also caused by *T. rhodesiense* occurred in the Ufipa area of the Western fly-block. The first cases were found in 1924 but MACLEAN (1927) stated that there was ample evidence to show that the disease had been there at least since 1921 and he mentions that European hunters, who visited Ufipa in 1915 reported that a disease resembling sleeping sickness was then present in the forest villages. The information was very vague and the Africans maintained throughout that the disease was new to them. MACLEAN (1926) also stated that a fatal disease established itself in the village of Tumbu in 1920 or 1921 and his account illustrated with a map, traces very clearly the spread of the disease from village to village spreading outwards from Tumbu. By 1924 the whole of the southern part of the fly block on both sides of the River Rungwa was infected.

The disease spread northwards reaching the southern and western sides of Tabora by 1928 and north of Tabora in 1927. MACLEAN (1928) observed that of 40 known cases in this area, there was not a single one who did not come within infective range of another case and he records another instance of spread from village to village. He stated that all the available evidence pointed to a man-fly spread.

Kahama was infected in 1928 and here again MACLEAN (1928a) showed how the disease spread outwards from the villages of Mtema and Msala, where the first cases seem to have occurred.

From Kahama the disease spread (1) northwards into western Mwanza, (2) north-westwards into Baharamulo district and (3) westwards into Kibondo and Kasulu districts, reaching these areas in 1930. The further spread of the

Vol. 45 No. 5 at the foot of p. 383 in the *Summary of Recent Abstracts, Trypanosomiasis*, the following sentence "The author [VAN HOOFF] thinks that melarsen oxide is useful for the treatment of patients with resistant strains (a conclusion not shared by LOURIE)" does not correctly represent the views of Lourie, who shows, on p. 413 of the same issue, that he has confirmed van Hooft's findings. The phrase in brackets, therefore, should be deleted.

Vol. 45 No. 5, p. 388 in the abstract of the papers by SHORTT *et al.*, the reference to HUFF AND COULSTON in line 4 should read (*J Parasitology* 1947 v 33 No. 6 Sect. 2 (Supp.) 27).

Vol. 45 No. 5 p. 418 in translation of MURANO's title for Banti read Bantl.

Vol. 45 No. 6, pp. 539-540, in the abstract of the papers by MARQUARD, the words "it was found that the lysoctithin formed by the lecithase in the blood suspensions were stabilized. It is believed that venom is the stabilizing substance" should read "it was found that blood suspensions were stabilized. It is believed that the lysoctithin formed by the lecithase in the venom is the stabilizing substance"

Vol. 45, No. 7 p. 646, the footnote to Tropical Ophthalmology article should read "For the 49th of this Series see Vol. 44 pp. 1093-1095"

Vol. 45 No. 12, p. 1100, in title to last abstract for KLAZEN, H. W read BECKHUIS, H. J

disease was limited by the fact that it had reached the Lake shore on the north, and the open, fly-free country on the boundary of the Belgian Mandated Territory in the west.

There was a steady progression of the disease through this extensive fly-block, with an interval of about two years before each new area was infected, and a further interval of about two years after infection before the disease reached epidemic proportions. Owing to the control measures undertaken, it is not known when the epidemics would have reached their peaks.

Mkalama—Sleeping sickness was next diagnosed in Mkalama district in 1932. MACLEAN, in an unpublished official report, gives the following history of the first case in this area. A wife had run away with another man, and the husband set out to look for her. In 17 months' travel he passed through Mwanza, Kahama, Tabora, Ufipa and down to the coast areas, and he then returned home. Within a few weeks he was ill and died, and a few months later a number of cases of sleeping sickness (*T. rhodesiense*) had been diagnosed in his village and in the valley in the immediate neighbourhood.

Ukerewe—A sharp, but limited, outbreak started in the Ukerewe peninsula of Lake Victoria, in October 1939 (the hottest month of the year). It is not known how the disease was introduced, but there is frequent traffic of Africans between this area and the infected areas of Maswa and Musoma.

Babati-Kondoa—In October, 1943 (again the hottest month of the year), cases of sleeping sickness were diagnosed amongst the African labourers working on European farms in the Babati area of the Northern Province. Most of these labourers were aliens from other districts, who had come in search of work, and at least one party of Waha had come from the western part of Kibondo district and had travelled through the Kibondo-Kahama-Mkalama infested areas before arriving at Babati.

The disease is spreading southwards into the north-western corner of Kondoa-Irangi district. There are records of African inhabitants of Kondoa travelling from Arusha through the Babati area and being diagnosed on their return home, several men, previously healthy but later infected, had been working on bush-clearing at the southern end of the Babati area.

South-Eastern Fly Block—In December, 1924, an outbreak of the disease occurred in Liwale district, about 50 miles north-east of the district headquarters. This small outbreak was fully described by DYE (1927). In the memory of the older inhabitants the area had a bad reputation, villages built there had sooner or later to be abandoned owing to sickness, which ceased when the inhabitants took up new sites farther away. As, however, the valleys possessed good soil and water in a dry and unprofitable area, the people usually made attempts to return, although certain sites, favourable in themselves, had become definitely banned. That sleeping sickness was well known was shown by the fact that it possessed a local name. Although Dye does not discuss how it was introduced into the area, he was certain that the disease, which had started in the village of Namabao, was spread from village to village by infected human beings. The disease eventually disappeared, apparently as a result of a further spontaneous abandonment of the whole area by the people.

In March, 1936 sleeping sickness was found at Madaba, 100 miles due north of the district headquarters, and the present author obtained the following history. Saidi Idunda, who had lived on the River Mbemkuru for about a year returned home in September, 1935, began to have fever and died in November, 1935. When he was dying, he was housed by his brother-in-law Abdullah Likurunju. A short time after Saidi's death, Abdullah fell ill and then his nephew, grand-daughter and his wife also did so. Trypanosomes being found in the blood of the last-named in April, 1936. Ali Mbiriri visited Abdullah in January, 1936 before the latter's death, and returned home with

fever and died and after his return his father fell ill and trypanosomes were found in his blood. Further patients all gave a history of having lived with or visited one of the above patients. The disease eventually spread widely in the area cases being diagnosed as far west as the River Mbarangandu, which is the boundary between Liwale and Mahenge district, and a favourite resort of fishermen of both areas.

The River Mbemkuru area was probably infected during the period of the German occupation, when sleeping sickness spread from the Rovuma to Kibwa and the disease appears to be endemic there, as cases have been found from 1924 onwards, whenever this inaccessible area has been surveyed. There is no doubt that the 1936 outbreak in Liwale was the direct consequence of the introduction of the disease from this area by an infected human being.

Rufiji.—Only three cases, diagnosed in 1934, 1936 and 1938, have so far been reported in Rufiji district. The last of these is particularly interesting, as the patient had lived in the village of Bagala for over a year. During September 1938, he had visited the village of Jumbe (sub-chief) Saldi Rupia in Mahenge district and he fell ill with trypanosomiasis in October on his return home. To reach Saldi Rupia's village, he would have had to travel through the northern part of the infected Liwale area.

Mahenge.—Isolated cases of trypanosomiasis were recognized in 1925, 1928 and 1930. The last patient was a child 2-3 years old who had visited a village on the Songea road where the local track from Liwale joins the main road.

The first case of the present outbreak, however, was diagnosed in April 1939. The patient was a Game Scout who had been stationed for some time at the village of Jumbe Saldi Rupia (see above). The next case in August was in a mission teacher at Mchombe mission. Three cases were diagnosed in September at the southern edge of the district, all of the patients gave a history of having visited Liwale district. In November, a hut counter living on the River Kilombero in the north-western corner of the district was found to be infected and in December in the same area, a relative of the teacher from Mchombe was diagnosed. The disease subsequently spread all over the southern part of the district, although in the north-west corner it remained localized.

Whether the disease was introduced to the village of Jumbe Saldi Rupia by the Rufiji traveller or whether the village was already infected by intercourse with the Liwale area, remains unknown. By analogy with the spread of the disease in the western fly-block, with the two years' lapse before successive areas were infested, one would suspect that Saldi Rupia's village was already infected in 1938 from Liwale and that it was the chief cause of the spread of the disease to Mahenge in 1939.

Southern Province.—Up to 1936 the cases which were recorded in the Southern Province were either in Africans from Portuguese East Africa, or else in local Africans who had visited that country.

When resettlement was taking place in Mahenge in 1940 many of the peoples of the southern part of the district moved into bush villages in Tunduru and Masasi districts, and there was a sharp rise two years later in the number of cases diagnosed in the northern parts of these districts. Some of them particularly in Masasi district may also have been infected on the River Mbemkuru.

Lake Tanganyika.—The first cases encountered in this area since the British Administration took over the Territory were found in 1924. Several of them occurred either in natives of the Congo or in others who had recently visited infected areas situated in Belgian territory (TANGANYIKA TERRITORY *Ann. Med. Report* 1925-23). The infection was caused by *T. gambiense*. Since then, sporadic cases were found between the Anglo-Belgian border and Tongwe,

where the disease appeared to be endemic (MACLEAN, 1927, 1930) No cases were found south of this, though a thorough search had been made since October, 1925

In 1938, cases of sleeping sickness began to be recognized at Karema, and on the southern half of the Lake. The infection of a European Telegraphic Inspector in an area south of Karema led to an extensive examination of the area, when it was found that the infection was of the *rhodensis* type. This was an extension westwards of the Ufipa outbreak, through the *morsitans* fly belts, until the disease had reached the Lake shore. A total of thirty-one officials and non-Africans have been infected since 1922. This number is made up of seven European Officers, one Sub-Assistant Surgeon and five African subordinate staff, all Government officials, and ten Missionaries, four miners, two other Europeans and two Asian traders.

4 Treatment

MACLEAN and FAIRBAIRN (1932) recorded the results of treatment of 719 cases of *rhodensis* sleeping sickness, the patients were kept under prolonged observation. In Maswa district, where patients came for treatment relatively late, of 131 patients treated, twenty-one (16 per cent) were cured after an observation period of more than six and a-half years. In the Tabora (epidemic) area, where patients came for treatment relatively early, of 588 patients treated, two hundred and eighty-three (48.2 per cent) were well and probably cured, after an observation period of not less than two years and five months. FAIRBAIRN (1944) has recorded the present methods of treatment and he has emphasized that a prognosis can only be given if the cerebrospinal fluid protein has been estimated at the beginning of treatment and during an adequate follow-up period.

In any outbreak of sleeping sickness in a new area, the first patients seen are usually at advanced stages and it takes some months before the results of treatment, and of propaganda, have any effect in making patients come earlier for treatment. The cure rate of 48 per cent recorded for the Tabora epidemic is about the best one can expect in any large epidemic, and it is considered that a minimum of 11,500 of the 23,955 patients diagnosed between 1922 and 1946 have died, or will die. This is a serious loss to a country which is already underpopulated.

5 Control Measures

As soon as the disease was found in an area dispensaries were built, and staffed with properly trained persons, equipped with microscopes. Treatment was soon started. Treatment alone, however, can never control or stop an epidemic, and was merely palliative until more positive preventive measures could be planned and put into operation. These control measures were based on the principle of breaking the contact between man and the tsetse fly. *Maswa*—In 1922, approximately 5,000 people were removed from the tsetse bush and resettled in the open country, but by communal bush-clearing considerable congestion in the open country, and sufficient land was made available for all the people. Since 1935 only one case (in 1938) has been diagnosed in the district. *Ukerewe*—When the Ukerewe outbreak began, the Tsetse Research Department applied in the field their experimental method of 'discriminative bush clearing'. This implies the clearing of only those parts of the bush which form the essential tsetse habitat. During 1940-42, 118 square miles were treated involving the removal of 4,600 acres of hard-pan vegetation, or only 6 per cent. of the total area of bush (BAH, 1943). The tsetse was eliminated in parts or

fever and died and after his return his father fell ill and trypanosomes were found in his blood. Further patients all gave a history of having lived with or visited one of the above patients. The disease eventually spread widely in the area cases being diagnosed as far west as the River Mbarangandu, which is the boundary between Liwale and Mabege district and a favourite resort of fishermen of both areas.

The River Mbenkuru area was probably infected during the period of the German occupation when sleeping sickness spread from the Rovuma to Kibwa and the disease appears to be endemic there, as cases have been found from 1924 onwards, whenever this inaccessible area has been surveyed. There is no doubt that the 1936 outbreak in Liwale was the direct consequence of the introduction of the disease from this area by an infected human being.

Rufiji.—Only three cases, diagnosed in 1934, 1936 and 1938, have so far been reported in Rufiji district. The last of these is particularly interesting as the patient had lived in the village of Bagala for over a year. During September 1938, he had visited the village of Jumbé (sub-chief) Saidi Rupia in Mabege district, and he fell ill with trypanosomiasis in October on his return home. To reach Saidi Rupia's village, he would have had to travel through the northern part of the infected Liwale area.

Mabege.—Isolated cases of trypanosomiasis were recognized in 1925, 1926 and 1930. The last patient was a child 2-3 years old who had visited a village on the Songea road where the local track from Liwale joins the main road.

The first case of the present outbreak, however, was diagnosed in April 1939. The patient was a Game Scout who had been stationed for some time at the village of Jumbé Saidi Rupia (see above). The next case, in August, was in a mission teacher at Mchombe mission. Three cases were diagnosed in September at the southern edge of the district all of the patients gave a history of having visited Liwale district. In November a hut counter living on the River Kilombero in the north western corner of the district was found to be infected and in December in the same area, a relative of the teacher from Mchombe was diagnosed. The disease subsequently spread all over the southern part of the district although in the north-west corner it remained localized.

Whether the disease was introduced to the village of Jumbé Saidi Rupia by the Rufiji traveller or whether the village was already infected by intercourse with the Liwale area, remains unknown. By analogy with the spread of the disease in the western fly-block, with the two years lapse before successive areas were infested, one would suspect that Saidi Rupia's village was already infected in 1938 from Liwale and that it was the chief cause of the spread of the disease to Mabege in 1939.

Southern Province.—Up to 1938 the cases which were recorded in the Southern Province were either in Africans from Portuguese East Africa, or else in local Africans who had visited that country.

When resettlement was taking place in Mabege in 1940 many of the peoples of the southern part of the district moved into bush villages in Tunduru and Masasi districts, and there was a sharp rise two years later in the number of cases diagnosed in the northern parts of these districts. Some of them, particularly in Masasi district may also have been infected on the River Mbenkuru.

Lake Tanganyika.—The first cases encountered in this area since the British Administration took over the Territory were found in 1924. Several of them occurred either in natives of the Congo or in others who had recently visited infected areas situated in Belgian territory (TANGANYIKA TERRITORY *Ann. Med. Report* 1925 23). The infection was caused by *T. gambiense*. Since then, sporadic cases were found between the Anglo-Belgian border and Tanganyika.

where the disease appeared to be endemic (MACLEAN, 1927, 1930) No cases were found south of this, though a thorough search had been made since October, 1925

In 1938, cases of sleeping sickness began to be recognized at Karema, and on the southern half of the Lake The infection of a European Telegraphic Inspector in an area south of Karema led to an extensive examination of the area, when it was found that the infection was of the *rhodesiense* type This was an extension westwards of the Ufipa outbreak, through the *morsitans* fly belts, until the disease had reached the Lake shore

A total of thirty-one officials and non-Africans have been infected since 1922 This number is made up of seven European Officers, one Sub-Assistant Surgeon and five African subordinate staff, all Government officials, and ten Missionaries, four miners, two other Europeans and two Asian traders

4 Treatment

MACLEAN and FAIRBAIRN (1932) recorded the results of treatment of 719 cases of *rhodesiense* sleeping sickness, the patients were kept under prolonged observation. In Maswa district, where patients came for treatment relatively late, of 131 patients treated, twenty-one (16 per cent) were cured after an observation period of more than six and a-half years In the Tabora (epidemic) area, where patients came for treatment relatively early, of 588 patients treated, two hundred and eighty-three (48.2 per cent) were well, and probably cured, after an observation period of not less than two years and five months FAIRBAIRN (1944) has recorded the present methods of treatment and he has emphasized that a prognosis can only be given if the cerebrospinal fluid protein has been estimated at the beginning of treatment and during an adequate follow-up period

5 Control Measures

As soon as the disease was found in an area, dispensaries were built, and staffed with properly trained persons, equipped with microscopes treatment was soon started Treatment alone, however can never control or stop an epidemic, and was merely palliative until more positive preventive measures could be planned and put into operation These control measures were based on the principle of breaking the contact between man and the tsetse fly

Maswa—In 1922, approximately 5,000 people were removed from the tsetse bush and resettled in the open country on the edge of the bush This caused considerable congestion in the open country, but by communal bush-clearing during 1926-28 the congestion was relieved and sufficient land was made available for all the people Since 1935, only one case (in 1938) has been diagnosed in the district

Ukerewe—When the Ukerewe outbreak began the Tsetse Research Department applied in the field their experimental method of discriminative bush clearing This implies the clearing of only those parts of the bush which form the essential tsetse habitat During 1940-42, 118 square miles were treated, involving the removal of 4,600 acres of hard-pan vegetation or only 6 per cent of the total area of bush (BAX, 1943) The tsetse was eliminated in parts, or so

reduced in numbers in other parts, that the outbreak ceased although the people had remained dispersed in their hamlets.

Babati—In Babati, the method employed in 1944 was to remove the people and resettle them in open country. A measure of success was obtained, but the open country has not yet been sufficiently enlarged. Many of the cases now being diagnosed occur in people who surreptitiously return to the infested bush to collect the bananas, coffee and pawpaws which had to be left behind when they were resettled.

Remainder of the Territory—In the remainder of the Territory the policy adopted by MACLEAN was to make fly free settlements in the fly-bush. The aim was to have at least 750–1 000 taxpayers in each settlement the larger figure is preferable, but many of the earlier settlements had considerably less for various administrative reasons. Allowing a family of 3–5 persons per taxpayer this meant a total population of approximately 2,800–3,500 people in each settlement.

The land selected for resettlement was usually a piece of virgin *swambo* and it had to be of such size as to allow of 16 acres of good agricultural soil (excluding hills swamps, etc.) per taxpayer with adequate water supplies. As the area was a virgin one and usually heavily covered in bush, it took up to 4 years or more to clear properly the first 4 acres per taxpayer and it would take up to 12–15 years to clear the whole 16 acres per taxpayer with all the work being done by an annual turn-out of communal labour. The incidence of the disease was only affected therefore, about 2–4 years after the people had been resettled. FAIRBAIRN (1943) has given a full account of the details in making these resettlements. Table 1 shows the number of settlements made in each area.

TABLE 1

The number of settlements made and the number of people moved each area.

| Area | No. of Settlements | Year resettled | Taxpayers moved | Family per Taxpayer | Total people moved approximately |
|------------|--------------------|----------------|------------------|---------------------|----------------------------------|
| Masua | to open country | 1925 | | | 5,000 |
| Uda | 10 | 1925/27 | minimum of 8,546 | 3.3 | 28,500 |
| Tabora | | 1926/27 | | 3.3 | 4,300 |
| Kahama | | 1928/29 | | 3.3 | 44,700 |
| Kibondo | 4 | 1933 | 13,848 | 3.3 | 17,600 |
| hamalo | | | | | |
| Biharawulo | 6 | 1933/34 | 4,112 | 3.3 | 5,400 |
| W. M. area | 6 | 1934/36 | 1,541 | 4.0 | 26,000 |
| Mabenge | 9 | 1941/45 | 6,497 | — | 1,372 |
| Babati | 1 | 1944 | 420 | — | 8,000 |
| Livale | 1 | 1945 | 2,000 | — | |
| Total | 48 | | 28,656 | | 128,872 |

Approximately 140,000 people have been removed from isolated bush hamlets and resettled, either in settlements or in open country. By referring to Appendix I, it will be seen that such resettlement had a marked influence on the number of cases of sleeping sickness diagnosed in subsequent years.

Maclean has often been severely criticized for making settlements in the fly-bush, particularly as many of them were 150 miles or more from the railway and administrative headquarters and the roads to them are often closed for 6 months or more during the rains. But there are a number of points which the critics have overlooked.

Sleeping sickness occurs in a population which is widely dispersed in isolated hamlets in the fly-bush. It is considered that the condition most favourable to an epidemic is a density of population of 5 to 25 taxpayers (*viz* 16 to 80 people) per square mile. With a density of less than 10 people per square mile the disease can occur, but the population is usually so scattered that the infection is self-limited while with a density of 100 people or more per square mile, many of the villages are large enough to protect themselves from tsetse by the clearings made for their farms.

By the very nature of things, the people who elect to live in such widely scattered conditions are the most primitive in the Territory. They are the hunters who do little agriculture, or else the malcontents and the very conservative who desire to escape from tribal authority and from the restrictions and controls of progressive administration. MACLEAN (1929b) has ably summarized the position, and his paper should be consulted. Despite their primitive outlook, these very same people have an intense attachment to their tribal lands, and refuse to be moved out of their tribal area. They had, therefore, to be settled on their own land. It was difficult enough for the administrative officers to organize the present settlements, it would have been impossible to make settlements by moving the people right out of their tribal area.

Where a Native Authority had enough people to make one or more settlements of the correct size, these could be sited anywhere within the tribal lands. But where the people concerned were too few to make a settlement on their own, they were usually moved to the boundary of their area and joined up with a settlement of the neighbouring Authority, to make one large area with the tribal boundary running through the settlement.

Even at present there is some tendency to re-establish bush hamlets, and one of the main reasons for this is the fact that the head of a family moves out of a settlement, usually with the Chief's knowledge and often at his suggestion to settle on the boundary of the tribal area in order 'to guard the frontier' and see that the neighbouring Chief is not encroaching on the tribal lands.

When the Ufipa settlements were made in 1925-26 they were in Ufipa district (Sumbawanga) in the south-west of the Territory, and the settlements were therefore placed as far south as possible, in order to reduce the distances to be travelled with porters, on inspection and for the disposal of produce. Some years later the district boundaries were re-aligned, and the Ufipa settlements came under the administration at Tabora in the centre of the Territory and on the railway line. If Tabora had been the administrative headquarters in 1925, the settlements could have been sited at least 50 miles further north and nearer to the railway line, but it was now too late. The same remarks apply to settlements which are now in Chunya district but which were formerly under administrative charge from Tabora.

Finally, even if the people could have been moved out of the whole of the south-western fly-block and settled on or near the railway line, it would have involved leaving a vast area of country completely uninhabited and unadministrated, which was politically undesirable.

In two areas the disease appears to have been completely eradicated—in Maswa by settling the people in open country and in Ukerewe by eliminating the fly by discriminative bush clearing. The soundest control measure would appear to be a combination of the two methods, *viz*, settling the people in open country which has been enlarged to receive them and then discriminative clearing of the bush over a fringe half a mile wide, so that the people visiting the immediate forest for firewood, building poles, grass, etc., would not come in contact with tsetse.

6. The Sex Incidence of the Disease

The sex of the patients infected is shown in Table 2, the figures referring to cases diagnosed from 1936 onwards.

TABLE 2
The Sex of Persons suffering from Sleeping Sickness in the various Areas.

| Area | Males | Females | Boys (5-15 yrs) | Girls (5-15 yrs) | Infants male | Infants female | Totals |
|----------------------------|-------|---------|-----------------------|------------------------|-----------------|-------------------|--------|
| Ufipa | 733 | 88 | 32 | 9 | 1 (3 yrs) | — | 862 |
| Tabora | 221 | 34 | 9 | 3 | — | — | 268 |
| Kahama | 878 | 186 | 89 | 18 | 1 (3 yrs) | — | 1,169 |
| Western Mwanza | 67 | 10 | 4 | 2 | — | — | 83 |
| Kibondo | 843 | 142 | 36 | 17 | 1 (2 yrs) | 2 (3 yrs) | 1,040 |
| Kasulu | 217 | 43 | 6 | — | — | — | 266 |
| Biharamulo | 158 | 30 | 3 | 3 | — | — | 193 |
| Ikoma (Mwanza) | 301 | 128 | 21 | 14 | — | — | 462 |
| Ukerewe | 172 | 94 | 31 | 18 | 7 (1-4 yrs) | 1 (4 yrs) | 321 |
| Mkalama | 53 | 31 | 7 | 3 | — | 1 (3 yrs) | 97 |
| Dabati | 308 | 70 | 10 | 8 | 1 (1½ yrs) | 1 (3 yrs) | 425 |
| Kondoa | 82 | 47 | 5 | 3 | 1 (3 yrs) | — | 137 |
| Livale | 63 | 55 | 7 | 7 | 1 (2 yrs) | 1 (3 mths) | 136 |
| Mahenge | 116 | 64 | 16 | 6 | 2 (2 yrs) | 2 (10 mths) | 204 |
| | | | | | 4 yrs) | 4 yrs) | |
| Koroma (Southern Province) | 129 | 103 | 13 | 12 | 1 (3 yrs) | 2 (3 mths) | 259 |
| L. Tanganyika shore | 33 | 12 | 1 | — | — | 3 yrs) | 45 |
| | 4 461 | 1 104 | 258 | 118 | 16 | 19 | 5,967 |

In the old settlements of Ufipa, Tabora, Kahama, Western Mwanza, Kibondo, Kasulu and Biharamulo which were made between 1923 and 1936, there was a marked preponderance of males, the proportion of adult men varying from 79.2 to 85.0 per cent. with only 5 children aged 2-3 years infected in a total of 3,820 cases (0.13 per cent.) In these areas, it is the men who leave the settlements to hunt to collect beerrax and to transport produce and they are often accompanied by boys of 12-15 years of age.

On the other hand in the areas of Ikoma, Ukerewe, Mkalama, Kondoa, Lindi, Mahenge and Southern Province where epidemic conditions prevailed for a greater part of the period under consideration, the proportion of women was high varying from 27.3 to 40.4 per cent. with 21 infants and children aged from 3 months to 4 years infected in a total of 1,617 cases (1.3 per cent.) The fly was, therefore, present in the huts and in the immediate surroundings, where the women were at work.

Three infants, 3, 8 and 10 months old, were infected, as well as quite a number of other small children, and the incidence in infants and children would have been greater had the records of the Kahama epidemic of 1928-29 and of the Kibondo epidemic of 1933-34 been available. There was no evidence in our experience that infants had any inherited immunity. Whether they were infected or not depended upon the closeness with which they were brought into contact with the fly.

DURK (1923) in his report on the Maswa epidemic stated that the majority of the cases seen were in adults, both men and women and that the disease was rare in young people below the age of fifteen and exceedingly rare in young children. He stated that the age distribution thus corresponded to what

observers in the Congo had learnt to associate with human trypanosomiasis in epidemic, as opposed to endemic, form. In Tanganyika Territory, however it is characteristic of epidemics that a high proportion of women, children and infants are infected.

7 Variation in the Incidence of the Disease

A Monthly Variation

The effect of temperature on the transmissibility of the polymorphic trypanosomes by *Glossina* has long been known. KINGHORN, YORKE and LLOYD (1913) showed that the earlier stages of the development of the trypanosome in the fly could occur at a comparatively low temperature (60°F , 15.6°C), that the trypanosomes could persist in this stage for at least sixty days without the salivary glands being invaded, but that for the completion of the cycle it was necessary for the temperature to which the flies were subjected to be raised to a considerable extent ($75^{\circ}\text{--}85^{\circ}\text{F}$, $23.9^{\circ}\text{--}29.4^{\circ}\text{C}$). They also found that the percentage of infected "wild" flies caught in the Luangwa Valley was greater in the hot than in the cold season, and an examination of their Table 13 shows that the highest percentages were found when the mean external shade temperature was $79.0^{\circ}\text{--}87.1^{\circ}\text{F}$ ($26.1^{\circ}\text{--}30.6^{\circ}\text{C}$) while between 67.2° and 77.5°F ($19.6^{\circ}\text{--}25.3^{\circ}\text{C}$) no infected flies were found. LLOYD (1930) and TAYLOR (1932) had shown that it was possible in the laboratory to obtain greatly increased infection rates by incubating the tsetse flies at $33^{\circ}\text{--}37^{\circ}\text{C}$. A more recent finding by BURTT (1946) was that when pupae of *G. morsitans* were incubated at 30°C the flies that emerged gave much greater transmissibility rates than flies which had come from pupae kept at normal (and lower) laboratory temperatures.

At Tinde Laboratory it has been found that the percentage of flies infected in each month is correlated significantly with the mean maximum temperature to which the flies are exposed. The highest transmissibility rate is obtained in October at the height of the hot, dry season, and the lowest in May-July, in the cool period after the rains.

Table 3 shows the number of cases of sleeping sickness diagnosed in each month totalled over a period of years and the average monthly mean maximum temperature recorded at the Meteorological Station Tabora, for the period 1936-46. Tabora is situated in the centre of the western fly-block, at an altitude of 4 000 feet, and the temperatures recorded there are representative of the whole of the area.

In the western fly-block as a whole there was a very significant correlation between the monthly mean maximum temperature at Tabora and the number of cases of sleeping sickness diagnosed in the following month ($P < 0.1$), and this level of significance was maintained when the figures for individual areas were examined, with the single exception of Ufipa. In the Kibondo-Kasulu-Biharamulo areas, taken together there was also a very significant correlation ($P < 0.1$) between the maximum temperature and the number of cases diagnosed two months later. This correlation is shown diagrammatically in Fig. 1.

No suitable temperature data were available for comparison with the cases in the remainder of the Territory. The increase in the number of cases noted in the hot dry season is thus probably due to the combined effects of occupation, leading men into the fly bush and an increased proportion of infected flies encountered, owing to the high temperatures of that period.

B Yearly Variation

The Tsetse Research Department take as their index of the fly population in the bush the number of old male *G. swynnertonii* caught per 10,000 yards on fly

TABLE 2.
The monthly incidence of cases of Sleeping Sickness

The annual incidence of cases of leprosy is known in the Western Hemisphere to be relatively low, but this report indicates that at Filadelfia, Peru, the yearly average of these catches is given in Figure 1, which is drawn on a logarithmic scale, the exact values are shown to the right of the number of cases. The number of cases in the territory of the State of Filadelfia is shown in Figure 2.

In Fig. 2, which is drawn on a logarithmic scale, the catches of test cells in Shimmying are shown against the number of cases of sleeping sickness diagnosed in the whole territory. Statistical analysis shows that over the period 1930-45 there is a very significant correlation between the two ($P < 0.01$). When the year 1946 is included the correlation is lower, but still significant.

Fig. 2

Logarithmic graph of total population, Shinyarka and the number of cases of sleeping sickness diagnosed in Fanninka Territory

(P nearly equals 0.7) The outbreak in Koodoa Irangi may be responsible for the adverse effect of the 1946 figures on the total correlation. There is a suggestion of a cyclical variation, but the observations are too few.

A study of Appendix I shows that sleeping sickness has usually reached epidemic proportions in new areas in the same years that maximum numbers of cases have occurred in distant endemic centres (which might have a different species of fly) e.g. compare in 1932 Ikoma-Ufipa-Tabora with Kibondo in 1940 Kibondo with Ukerewe-Mahenge and in 1944 Kahama-Kibondo with Babati. Further in the years 1927-1937-38 and 1942-43 minimal numbers of cases occurred in widely separated areas. The yearly variation in the tsetse population is probably due to a long-term variation in climatic conditions. One of the climatic factors may be temperature, but there are probably other unknown factors at work over a long period. The variation in the number of cases of sleeping sickness may be directly correlated with the tsetse population (i.e. the more flies there are the greater the chance there is of being bitten and hence of more cases). On the other hand, the correlation may be indirect, through climatic conditions influencing both the tsetse population and the infection rate of the fly.

8. The Role of Game

In the foregoing study of sleeping sickness in Tanganyika Territory it has been shown that the introduction of the disease into an area can usually be traced to the arrival of a human being infected with *T. rhodesiense*. There is no need to postulate the repeated infection of man with *T. brucei* derived from game. It has been shown, however, that a strain of *T. rhodesiense* passed through sheep and antelope by cyclically infected *G. morsitans* was still infective for man ten and a half years after its removal from man (FAIRBANKS and BURTT 1946). The rôle of game is that when once the disease has been introduced into an area the game become infected with *T. rhodesiense* and they then act as reservoirs for maintaining the disease endemically.

The statement that game act as reservoirs for *T. rhodesiense* has been criticized on the grounds that this has only been demonstrated hitherto in the laboratory, and that *T. rhodesiense* has never been recovered from game in its natural state but this criticism has been answered.

MACKINTOSH (1944) reported an epidemic of Rhodesian sleeping sickness which began in November 1940 and swept through the Busoga and Samia districts of Uganda. In April 1943 Dr C. H. N. Jackson of the Tsetse Research Department, was working on the insect vector of this epidemic, and he was engaged in collecting tsetse flies in the Lugalla area of the Samia district. The area where the flies were caught had been cleared of all inhabitants at least year before the nearest human source of trypanosomes was about 3 miles distant from where the flies were found and the only persons entering the area were very occasional trespassers in search of fish and game. While collecting the flies one of Jackson's fly-boys from Tanganyika Territory became infected with sleeping sickness.

The flies caught were fed in batches of 100 on each of fifty clean laboratory bred rats, and it was estimated that 3,500 flies fed. When feeding was completed, the flies were killed and examined. One *G. palpalis* was found, and the rat on which this fly had fed was discarded all the rest of the flies were *G. palpalis*. Five rats were infected with polymorphic trypanosomes with incubation periods of 7 days in each case. The five rats were killed, 0.25 cc. of heart blood was mixed with 0.25 cc. of sterile normal saline and injected into the arm of each of five volunteers. Four of the men showed no reaction and their blood was negative up to the 10th day after inoculation when they were given treatment. On the 4th day the fifth man developed a painful swelling

at the site of the injection, on the 5th and 6th days his temperature was 102°F, and on the afternoon of the 6th day scanty trypanosomes were found in his peripheral blood. He was then given treatment. The volunteer was an employee of the Medical Department and lived at Jinja, where he was out of contact with the fly.

This experiment establishes the fact quite clearly that *G. pallidipes* was carrying a polymorphic trypanosome, infective to man and morphologically identical with *T. rhodesiense*. The area was as completely depopulated as anyone is ever likely to find for the purposes of such an experiment, and there is no doubt that the fly could have been infected only by feeding on an animal reservoir of the trypanosome.

Epidemiological evidence that game act as reservoirs for the human disease also comes from two areas in Tanganyika Territory. The River Ugalla, in the Tabora district, was depopulated in 1925-26 and except for an occasional foot-traveller, there are no human beings in the area during the six months of the wet season. Fifty miles to the east of Kibondo are the native-worked salt deposits of Kinyora which are only visited (illegally) for 2-3 months at the end of the dry season. In both of these areas cases of sleeping sickness occur as soon as the fishermen return to fish the Ugalla pools in June, or the people of Kibondo district go to the salt deposits in August.

Dr C H N Jackson, in a personal communication states that in the field, the average length of life of male *G. morsitans* varies from about 2 weeks in the hottest time of the year up to 5 or 6 weeks during the rains. The extreme span of life is believed to be about 12 weeks. The female flies live for an average of perhaps 2 months. It is not possible for a fly which has been infected from a human being in November of one year to be able to infect a human being in June of the following year. The infected flies which are present in June of any year can only have obtained their infection from any existing game which were acting as reservoirs of the parasite.

It is therefore, understandable why the disease has not died out in Tanganyika Territory although resettlement has controlled its incidence. So long as it is necessary to make settlements in fly-bush containing an abundance of game, visits to or through the bush will be dangerous and so long as game are present and act as reservoirs of the parasite, the disease can only be reduced in incidence, not eliminated.

Acknowledgments—I have to thank my colleague Dr K C Willett, for the large number of statistical analyses which he made, and for drawing the figures and map. Dr C H N Jackson of the Tsetse Research Department, for his help and criticism in the statistical work. Mr W H Potts of the Tsetse Research Department for providing the figures of the tsetse population and for giving his permission to publish them and the Hon the Director of Medical Services Tanganyika Territory for his permission to publish this paper.

SUMMARY OF RECENT ABSTRACTS *

I CHOLERA

Epidemiology Aetiology

STOWMAN (p 208) has written an account of the world cholera situation in the summer of 1946, in China at least 16 provinces were affected, and Thailand and parts of India had a bad year. The same author (p 421) makes the point that the 1946 epidemic of cholera in China was one of the most extensive ever recorded in the Far East. He thinks that there are two completely distinct main foci, in the Yangtze and Kwangtung areas respectively, the type of disease seen in the former is more amenable to treatment than that seen in Kwangtung.

PETERSON (p 1065) shows that the risk of infection in an outbreak in China was about 36 times as great in household contacts as in the general population, and about 5 times as great in unvaccinated as in vaccinated contacts. The information on which these figures are calculated is admittedly so likely to be erroneous that he claims only that the figures are rough indications.

He (p 1065) found in China that the average period required for stools to become negative for *V cholerae* was 5.4 ± 2.3 days from the onset of symptoms. In no case were stools positive beyond the 17th day.

PANJA and GHOSH (p 998) found true *V cholerae* in 16 of 524 samples of water from the river Hooghly they used the candle-boric-peptone-water method.

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947 v 44. References to the abstracts are given under the names of the authors quoted and the pages on which abstracts are printed.

GALLUT (p. 421) contends that the true cholera vibrio is not Voges-Proskauer negative, as it is usually held to be, but that it can produce acetylmethylcarbinol in sensitive media. It produces considerably less, however, than the El Tor and the Celebes vibrios, and this fact can be used (as well as the haemolysis test) as a basis for differentiation. In a highly technical paper the same author (p. 660) discusses the oxidation-reduction potential of the cholera vibrio under various conditions of cultivation. The original paper should be consulted for details.

SKIN and his colleagues (p. 206) discuss in two articles, the biochemistry of the cholera-red reaction. These papers cannot satisfactorily be summarized, and should be read in the original.

BRUMMAN (p. 660) has isolated a non-agglutinable vibrio from a patient with typical (but not fatal) cholera in Tonking.

Pathology Treatment

CHATTERJEE (p. 966) has continued his studies of the bone marrow in fatal cases of cholera, and shows that the characteristic finding is the very great dilatation of the capillaries and sinusoids, which was most remarkable in the bone marrow but which was also found in many organs. This dilatation, it is suggested, may partially explain the collapse which is a feature of cholera.

In the report of the Scientific Advisory Board of the Indian Research Fund Association for 1946 (p. 966) there is a statement of the results of trials of treatment with various sulphonamides. There is little to choose between the results with sulphaguanidine, sulphasoxidine, sulphadiazine and controls given a placebo so far as case-mortality is concerned. CHU HUANG and their colleagues (p. 423) have used sulphaguanidine and sulphadiazine in the treatment of a small number of patients with cholera, in addition to intravenous salines. The results indicate that the average duration of diarrhoea was reduced, but there was no remarkable effect on the time of disappearance of vibrios from the stools. The effects of the two sulphonamides were about equal.

RELMAN *et al.* (p. 423) in China treated a few patients with streptomycin but do not report any striking favourable results. They think that the important clinical feature of cholera is not intoxication but dehydration and that correction of the latter is the chief therapeutic need. If treated properly in this way cholera becomes much less fatal, with a case-mortality rate of only 5 per cent. Streptomycin and the sulphonamides showed no significant effect in reducing the duration of the carrier state in convalescence. The authors think that cholera is not only water-borne, but is also transmitted directly from case to case: the latter mode of spread was more important than the former in the outbreaks they describe.

PETERSON (p. 1085) has attempted to evaluate the value of sulphadiazine prophylaxis of cholera in China, but the number of cases which occurred in the trial and control groups was so small that no final conclusions were possible.

Vaccination Control

BURROWS *et al.* (p. 422) in their introduction to a study of immunity to cholera, comment on the fact that there is little positive evidence on the subject of the efficacy of vaccines but they conclude that the immunity produced may be in some small degree effective, though leaving much to be desired. The cholera vibrio in its infection remains within the lumen of the gut, that is, virtually outside the tissues of the body throughout the disease. The same authors (p. 422) have investigated the structure of the O antigen of the cholera vibrio and describe three effective components, A B and C. A is group-specific B and C are type-specific for Inaba and Ogawa strains. The possible

are, therefore, A, AB, AC and ABC, the last is the Hikojima inter-ate type. The authors propose nomenclature according to these letters, and of the old names, they note that the O group I of Gardner and Ven-uman contains group-specific antigen A, and that there is no immunological action between cholera vibrios and El Tor vibrios of O group I.

The Report of the Scientific Advisory Board of the Indian Research Fund 946 (p 998) it is stated that of 320 strains of *V. cholerae* isolated, 88.1 per cent were of Ogawa type, and 11.9 per cent Inaba.

INJA and DAS (p 999) have made a preliminary study of the intradermalulation of cholera vaccine in man, and report encouraging results. BODWARD (p 79) reports that a number of men in the U.S. Navy developed symptoms suggesting appendicitis after, and apparently owing to, injection of cholera vaccine.

SEAL (p 208) notes that in part of Bengal there were 27 outbreaks of cholera in one year. He describes the detailed instructions given to patients and attendants, in relation to treatment (with sulphaguanidine) and prevention. Washing powder solution is used for domestic sterilization of discharges, and the hands, water and milk should be boiled and food should not be eaten.

Details should be sought in the original.

Charles Wilcocks

RABIES

ERARAGHAVAN, N. **Cultivation of Rabies Virus *in vitro*** [Correspondence] *Nature* 1947, June 7, 782

The author has previously reported [this *Bulletin*, 1947, v 44, 635] that the rabies virus will grow in a cell-free medium containing steamed sheep-brain extract, sheep serum, glycine and peptone. The addition of tryptophane (2 mgm per cc) stimulated the growth to 25 million MLD in place of 10 million MLD per cc. The addition of biotin, thiamin hydrochloride, pyridoxine hydrochloride, calcium pantothenate, nicotinic acid and riboflavin gave concentrations of 100 million to 50 million MLD per cc. By adding all these substances it was possible to dispense with the sheep-brain extract in the medium. With a medium containing 2.5 per cent glycine, 2 per cent sheep serum, 0.15 per cent peptone, 2 mgm per cent tryptophane, 2 µgm per cc each thiamin hydrochloride, pyridoxine hydrochloride, calcium pantothenate, nicotinic acid and riboflavin, together with 0.2 cc per 100 cc of biotin solution, concentrations of 5,000 million MLD per cc were obtained. The virus was also cultivated in a cell-free medium containing 5 per cent glycine, 0.3 per cent peptone and 4 per cent sheep serum. The successful cultivation of the biological agent of rabies in the cell-free medium indicated that it is not a virus in the ordinary meaning of the term. [See also this *Bulletin*, 1946, v 43, 194; 1947, v 44, 634.]

C. M. Wenyon

UBRY, G., LAFFARGUE, P. & PORTIER, A. **Deux cas d'accidents nerveux de la vaccination antirabique** [Two Cases of Neuroparalytic Accident after Anti-Rabies Vaccination.] *Algérie Méd* 1947, Feb, No 2, 169-72, 173-4, 175

The author describes two cases of neuroparalytic accident occurring after anti-rabies inoculation. It was possible to show that one of these was first caused by the rabies virus. The method employed was the classical one of giving daily inoculations of suspensions of rabbit cords of increasing virulence. The

NASCIMBENE A. & PREZIOSO A. La lotta antimalarica in provincia di Pavia (studio riassuntivo degli anni 1932-1945) [Antimalaria Campaign in the Province of Pavia.] *Riv Ital d'Igiene*. 1947 May-June, v 7 No. 3/6, 192-212 1 map & 2 charts. English summary (6 lines)

This is a description of the Province of Pavia, from a malaria standpoint, and of the activities of the Provincial Antimalaria Committee. There has been very little endemic malaria in recent years. In 1932, there were 144 notified cases in 31 communes in 1945 there were but 4 cases in 3 communes. In addition, there were numerous imported cases at the time of the Abyssinian war and during the world war. Very little has been done in the matter of anopheline control. Nearly all infections are due to *P. vivax*.

Vernon White

MATHIEU M. Le paludisme dans l'Atacora. Circonscription médicale de Natitingou Dahomey (Malaria in Atacora District (Dahomey)) *Bull Mèd de l'Afrique Occidentale F a para.* 1946, v 3 No. 2, 267-8

Three different tribes occupy the Atacora Circle which occupies an area of 22,000 square kilometres and possesses a total population of 148,000. The author was struck by the infrequency of mosquitoes there and, therefore, examined the degree of malarial endemicity in the region.

Figures of attendances at medical institutions from 1938 to 1945 indicated that the number of cases of malaria notified varied between 3 and 8 per cent. of all patients seen (from 9,214 persons examined in 1938 to 21,080 in 1945).

These figures are however only applicable to urban centres. The author therefore consulted the records of the local sector of the Mobile Hygiene Service, which indicated that the percentages of blood films found positive for malaria for 1943 to 1945 were respectively 50.12 (28,648 blood examinations), 51.87 (28,288) and 73.90 (55,046). The most recent parasit rate was therefore about 74 per cent.

Clinical malaria in children was frequent and serious and was caused entirely by *P. falciparum*. Splenic indices from children aged 2 to 12 years in three schools are given as 23.78, 14.31 and 11.17 per cent. [but it is noted that only 185, 35 and 170 children were examined].

The gametocyte rate varied between 12 and 14 per cent. The author fixed the Ross index at 50 [it is not stated whether the endemic index of Ross or the index of Ross of Brumpt is implied].

The author concludes that Atacora should be considered as an area of high endemicity and points to the danger inherent in the casual attitude of the inhabitants to malaria because of the comparative rarity of mosquitoes [the mosquito vectors are not mentioned].

H. J. O'D. Burke-Gaffney

HAIRSTON N. G. BANG F. B. & MAIER, J. Malaria in the Natives of New Guinea. *Trans Roy Soc Trop Med & Hyg.* 1947 July, v 40 No. 6, 795-807 5 figs. & 1 map.

An examination of spleens and blood smears was carried out in nine different areas of New Guinea. The results are tabulated. Over 4,000 natives were examined. Malaria was found to be hyperendemic in all areas but there was considerable variation in the intensity of transmission. In one village malaria was so intense that the incidence of palpable spleen was highest in the 0-5 age group. Older children had sufficient immunity to determine a lower spleen rate. The spleen rate of children in this village was 68 per cent. but it had

Malaria

Vol 45 No 1]

more malaria than had another village with a children's spleen rate of 94 per cent. These observations indicate the importance of classifying results according to age groups.

The authors consider the plasmodiometric index, measuring the parasite load of the population [see this *Bulletin*, 1943, v 40, 739] to be a useful adjunct to the standard survey, the positive blood smears are divided into categories according to the number of parasites found per 500 white blood corpuscles.

PAUL, J. H. & BELLERIVE, A. A Malaria Reconnaissance of the Republic of Haiti. *J. National Malaria Soc.* 1947, Mar., v 6, No 1, 41-67, 4 figs [13 refs.]

The Republic of Haiti occupies the western third of the second largest island of the West Indies, the remaining two-thirds constitute the Dominican Republic. The Gulf of Gonave almost bisects Haiti into two peninsulas. The country is mountainous. There is only one river of any size, the Artibonite. Most of the other streams are intermittent, nearly all are blocked at the mouth by sand or gravel bars, the resulting lagoons are productive of anophelines. The principal human settlements are on the coast near such streams. The population of the Republic is almost entirely Negro. The few whites and Asiatics are confined to the more important commercial centres. The economy of Haiti is about two millions. Port-au-Prince, the capital, has between 100,000 and 200,000 inhabitants, there are no other large cities. The economy of Haiti is purely agricultural. No reliable vital statistics are available.

In 1940, arrangements were made between the National Health Service and the Rockefeller Foundation to carry out a malaria survey of the whole republic. The field work was limited to an examination of schoolchildren. All schoolchildren were examined for splenomegaly. The blood of all children with enlarged spleens and of 25 per cent of children with normal spleens was examined. In villages with less than 50 schoolchildren all were examined for parasites. In all 31,285 children in 826 primary schools were examined. The spleen rate of children in schools at altitudes of less than 1,000 feet was 29.8, between 1,000 and 2,000 feet 13.5, over 2,000 feet 6.2 per cent. The highest spleen rate (20.6) and the largest average spleen of an area, the higher was the age group, 0-4. The higher the splenic index of an area, the higher was the incidence of parasitaemia both in those with normal spleens and in those with splenomegaly. For the country as a whole, children with normal spleens had a parasite rate of 21 per cent, the group with the smallest amount of splenic enlargement, palpable on deep inspiration, had a parasite rate of 68, parasite rates of 78, 80, 80 and 100 per cent were found in children with ascending sizes of spleen. Of all infections, 86.6 per cent were *P. falciparum*, 8.9 per cent *P. malariae* and only 1.9 per cent *P. vivax*. Only 2.6 per cent were mixed infections, slides were not ordinarily studied for more than five minutes.

Three species of anophelines were found. *A. albimanus*, *A. grabhami* and *A. vestitipennis*. *A. albimanus* was ubiquitous. It had a wide variety of breeding places, but preferred a sunlit situation. *A. vestitipennis* was found breeding only in one shaded swamp. *A. grabhami* was found in 19 of the 27 arrondissements breeding with *A. albimanus* or alone in streams or canals that were heavily shaded. Numerous dangerous breeding areas are man-made.

The clinical manifestations of malaria rarely arrest attention except among the infants of the community. The few areas of Haiti that are malaria-free are the higher mountain valleys and the south-west slopes where the rainfall is very low.

NIXTO CAICEDO M. Epidemia regional de malaria en la cuenca del Lago de Maracaibo 1942-1943 [A Regional Epidemic of Malaria in the Basin of Lake Maracaibo, Venezuela, in 1942-1943.] XII Conferencia Sanitaria Panamericana. Cuadernos Amerillos. Publicaciones de la Comisión Organizadora. No. 22. Caracas. 1946, June, 288+xx pp., 32 figs. on 1 pl., 8 maps (8 folding) & 43 graphs (10 folding) [23 refs.] English summary

This study of close on 300 pages, discusses in very considerable detail, and with a wealth of tables, charts, diagrams and other illustrations, a wide regional epidemic of malaria which occurred in Venezuela in 1942-43 and the measures applied against it.

The area concerned was the basin of the Maracaibo Lake in Zulia State.

Topographical and meteorological data are fully discussed: the level of the lake is inconstant and flooding into surrounding country leads to the formation of breeding places for mosquitoes. The local temperature averages about 82°F the humidity ranges from 70 to 85 per cent., and the rainfall varies greatly: an unusually heavy rainfall during 1942 preceded and contributed to the epidemic.

Sociological features are described and the incidence of malarial morbidity and mortality is discussed at length. The local distribution of anophelines is shown and it is noted that *A. albimanus* is more prevalent in the northern desert-like regions and *A. darlingi* in the southern jungle. It is stated that previous epidemics of malaria have shown some "para-quinquennial periodicity".

Full figures are given for the prevalence of anophelines in breeding places and dwelling houses in the city of Maracaibo: the oocyst rate was 5 per cent. The epidemic lasted from November until March, with a peak in January: during that period, 17,201 cases were actually recorded but it was estimated finally that the total was in the neighbourhood of 40,000.

In 7,869 blood films examined, an infection rate of 50.4 per cent. was found. In the town of Maracaibo, *P. vexans* prevailed, but *P. falciparum* was prevalent in 40 per cent. of the rural outbreaks seen.

The general mortality for Zulia State as a whole surpassed in 406 deaths the expected mortality according to the median and the mortality from both malaria and fever together exceeded by 473 the corresponding median.

The control measures adopted included free distribution of 50,000 complete quinine treatments and the usual methods of controlling *Anopheles* larvae and adults.

[This study represents a very fully documented account of an extremely large epidemic.] H. J. O'D. Burke-Gaffney

ANGELINI, G. Incertezza dei reperti di forme exoeritrocitarie dei plasmodi della malaria umana nel midollo osseo [Unreliability of Reports of Exoerythrocytic Forms of Parasites of Human Malaria in the Bone Marrow.] *Rev. di Parasitol.* Rome. 1947 Mar v 8 No. 1 3-18 [Refs. in foot notes.] English summary (7 lines)

The author examines the various records which have been made of the occurrence in smears of the bone marrow and other organs and in sections of tissues exoerythrocytic schizonts of human malarial parasites. He finds that ached portions of the cytoplasm of cells may simulate these stages, as occurs commonly in smears of bone marrow and comes to the conclusion that up to the present no reliable morphological record of these stages in human malaria has been made. The paper is a useful one in that it reviews the various papers which have been published on this subject. C. M. Haydon

Vol 45 No 1] **BLACK, R H** *The Consumption of Haemoglobin by Malaria Parasites* *Ann Trop Med & Parasit* 1947, Sept, v 41, No 2, 215-17, 8 coloured figs on 1 pl

Hitherto, evidence of the consumption of haemoglobin by malaria parasites has been derived from studies of (1) the pallor of infected red cells, (2) the formation of malarial pigment and its identification with haematin, and (3) respiration of plasmodia in monkeys.

The present author bases his study on the staining reaction of cyanol with haemoglobin in thin blood films containing malaria parasites, obtained from human and animal sources.

Cyanol (colour-index 715) in the reduced and colourless state, is oxidized in the presence of haemoglobin, which it stains blue. The author applied to blood films the method of staining haemoglobin in sections described by DUVV [this *Bulletin*, 1946, v 43, 1081], thus resulted in the washing out from red cells of the blue-stained haemoglobin, as Dunn's working reagent was found to be too acid for films.

The following procedure was therefore evolved —

Dunn's stock solution is prepared by dissolving 1 gm of cyanol in 100 cc of distilled water and adding 10 gm of zinc powder (C P) and 2 cc of glacial acetic acid, the mixture is boiled and quickly loses its blue colour.

The working stain is prepared immediately before use and consists of 5 cc of filtered stock solution (which has been kept over the zinc) and 0.5 cc of 3 per cent hydrogen peroxide.

As a counterstain, either 1 per cent aqueous safranin or diluted Leishman's stain was used. The different species of plasmodia showed distinctive staining with safranin, e.g., *P. gallinaceum* stains pink, while *P. vivax* is much lighter in colour. With Leishman's stain, there is no eosinophilic staining of the red cell, which remains cobalt green.

With the above methods, normal red cells stain cobalt green, parasites stain variously, e.g., pink (with safranin in *P. gallinaceum* infections), a faint-brownish yellow (with safranin and *P. vivax*), or blue-red (with Leishman's stain in *P. vivax* and *P. falciparum* infections). Safranin stains nuclei of fowl red cells a warm yellow-brown, malarial pigment, although prominent, apparently does not react with cyanol under the conditions described.

Young forms of parasites did not show any apparent loss of cyanol-staining material in the containing red cells, large rings showed a loss of green colour from their immediate neighbourhood. With amoeboid forms, the containing red cell showed only a little green colouration, the remaining green was distributed irregularly through the cell and was seen in the area not immediately in contact with the parasite. In *P. gallinaceum* infections, where there is little amoeboid activity, the green stain was absent only from the part of the cell occupied by the parasite.

Little if any, staining with cyanol was shown by red cells containing fully grown parasites such as *P. vivax* or *P. falciparum* gametocytes and *P. knowlesi* schizonts.

[All these forms are clearly shown in eight figures on a coloured plate.]

The usual appearances described in relation to infected red cells stained by the common methods are discussed, together with past views on the reduction of colour in red cells infected with malarial parasites. The author concludes, from the experiments described, that the actively amoeboid and more slowly growing parasites use the haemoglobin from most of the red cells, while the relatively inactive species merely use that in their immediate neighbourhood.

MACDOUGALL, Mary S. Cytological Studies of *Plasmodium* the Male Gamete.
J. National Malaria Soc. 1947 June, v 6, No. 2 91-8, 18 figs. on 5 pls.
 [37 refs.]

The study of the production of male gametes of *P. vivax* and *P. falciparum* has shown the author that chromosomes appear in the procoxa. The films were wet fixed and stained by Giemsa or haematoxylin. The earliest stage is that of four granular bands which are followed by four pairs of chromosomes arranged in a row. Next there occur two parallel bands which can be described as the pachytene stage. At this stage, the male gametes begin to form and four pairs of chromosomes are differentiated from the pachytene stage. Only one paired mass of chromatin enters each male gamete but each may represent more than one pair of chromosomes. When fertilization occurs, the male gamete with its pair of chromosomes enters the female gamete. In some cases sterile male gametes are formed without any chromatin and it seems that in certain strains of parasites these sterile males preponderate. In such cases mosquito infection is difficult. There are many gaps in the cycle and further studies are in progress. The paper is illustrated by a series of micro-photographs and line drawings. C. M. H. cryon

BAIRD, B. C. Abnormal Development of Malarial Oöcysts in *Anopheles stephensi*
Indian J. Malariology 1947 Mar. v 1 No. 1 129-32, 3 pls.

Three abnormalities were noticed in malarial oöcysts in the gut of artificially infected *Anopheles stephensi*. The black spores of Ross were found in 2 of 173, 13 of 354 and 4 of 61 mosquitoes fed on *P. vivax falciparum*, and malarial carriers respectively. In *falciparum* infections, oöcysts were occasionally found in the lumen of the gut instead of in the outer layer and it is concluded that such mosquitoes would not become infective. The third abnormality was seen in a *vivax* case where twin oöcysts occurred, probably as the result of two zygotes settling down close together. P. C. C. Garnham

PETERS, F. Die Stechmücken und ihre Bekämpfung. Teil I. Die Fiebermücken des Mittelmeergebietes. [Mosquitoes and their Control. Part I. *Anopheles* of the Mediterranean Region.] *Hyg. Zool.* Leipzig 1942, v 8, 150 pp. 170 figs. & 2 folding keys. [15 refs.]

The author has produced a general summary about the *Anopheles* of the Mediterranean region which is, at least in most respects, accurate and well illustrated. It would be suitable for a man who was to practise hygiene in that area, assuming that he had a slight general knowledge of entomology.

The introduction, which runs to about sixty pages, gives the characters of the genus *Anopheles* and the external anatomy of these insects with special reference to points used in determining species. The larger and more special part of the work deals with the Mediterranean species. The geographical limits of the region are defined in such a way as to exclude Persia, which is perhaps unfortunate. The author then gives a list of the species known to occur in the region, with lists of those found in the separate countries. This is followed by an account (generally two or three pages with text figures) of each species, with its diagnostic characters, geographical distribution, biology and importance in relation to malaria. The total number of species in the region is given as twenty counting *A. maculipennis* as one but the author points out that many of these are found only in a very limited part of the region, but that eight are of fairly wide distribution within it. One observes a few points on which the expert would disagree with the author for instance it is

Vol 45 No 1]

Malaria

stated that *A. superpictus* occurs in Spain and Portugal, which is probably an ancient error based on a misidentification. The work is concluded with keys to the adult and last larval stage, and with a list of principal books and monographs, which does not seem to have been very well selected.

MARAL, A D F & PENIDO, H M. Distribuição dos anofelinos no Vale do Rio Doce (Percurso da E F Vitória a Minas) Espécies Transmissoras da Malaria: [Distribution of Anophelines in the Neighbourhood of the Rio Doce] Rev Serviço Especial de Saúde Pública Rio de Janeiro 1947, v 1, No 1, 163-78, 1 map English summary

Studies of species of anophelines were made along a part of the Vitoria-Minas railway which runs from Vitoria on the coast of the State of Espírito Santo to Presidente Vargas in Minas Gerais. During 1943, 544,938 anopheline larvae and 10,973 adults were captured in human dwellings, an additional 1,022 adults were captured out of doors. Dissections of 1,118 stomachs and salivary glands indicated that *Anopheles darlingi* and *A. albiparvus* were naturally infected and were the vectors of malaria in that area. Infections were found in the stomachs of 75 per cent of 781 *A. darlingi* examined and 13 per cent of 226 *A. albiparvus*. In 7,094 blood films examined, malaria parasites were found in about 5 per cent. *P. falciparum* accounted for about one-half of these. Details of these figures and of species distributions are shown in seven tables.

H J O'D Burke-Gaffney

WEXLER, L, ADAMS, H V & GOLDBERG, L C. The Accidental Appearance of Quartan Malaria in a Therapeutic Malaria Treatment Center Amer J Syph 1947, Sept, v 31, No 5, 518-21, 2 figs

Quartan malaria is rare in the United States. The authors record the case of a Negro soldier, aged 36, admitted to a hospital in Augusta, Ga, for treatment of neuro- and cardiovascular syphilis. Fourteen days after admission, the patient complained of backache, joint pains and myalgia. His temperature exceeded 102°F that evening, fell to normal next morning and rose to 101°F in the afternoon. A blood smear was negative. For several days, a quotidian type of hyperpyrexia continued. On the 10th day of the fever (during which daily blood examinations had been made) quartan malaria parasites were found in the patient's blood. The malaria was terminated by treatment with chloroquine (S N 7618).

The origin of the infection is discussed. The patient was born in Alabama, and except for yearly visits to Panama City, Florida, between 1931-1940, had not left there until he entered the army in 1944. Thereafter, he served in Wyoming and Massachusetts and later in Europe (England, northern France, Luxembourg and Germany) until November 1945. On returning to the United States he lived for some weeks in Arizona and thereafter in his birthplace, Birmingham, Alabama. Nothing in his history could be attributed to malaria and he had never had any blood transfusions. The hospital ward to which he was admitted was a therapeutic malaria ward, where quartan and tertian strains were used. It was well screened and sprayed each month with residual DDT. As the patient had been receiving bismuth injections, the possibility of added that frequent use and exchange of syringes and needles takes place, because of routine penicillin therapy, however, sterile technique was always used.

Malaria is widespread in the south-eastern States, but the quartan parasite has "an unexplained spotty distribution." A delayed onset or a relapse of a

previous autochthonous infection was not found to be wholly compatible with the patient's history the final possibility is therefore considered that transmission was by an anopheline from a patient receiving therapeutic quartan malaria. Inspection proved the presence of *Anopheles quadrimaculatus*, *A. punctipennis* and *A. crucians* less than 850 yards from the hospital. It is stated that the incubation period of mosquito-induced quartan malaria varies from thirty to forty-nine days, yet exceptions may prove the rule, as in this reported case."

The authors re-emphasize the need for screening wards inhabited by patients receiving therapeutic malaria, and for providing mosquito nets where anopheline vectors are known to occur locally a conclusion already drawn by MARX and YOUNG (*Venereal Dis. Information* 1941 v. 22, 271). Strict asepsis is essential in such wards, since the possibility that this reported infection might have been introduced through syringe or needle cannot be completely dismissed.

HORRIG R. O. Induced and War Malaria. *J Trop. Med & Hyg* 1947 Aug., v. 50 No. 8, 150-59 6 figs.

This paper records the experience of a bridge-construction party of the German army 214 strong none of whom had been previously exposed to malaria. In the summer of 1941 they were near Larissa in Greece 116 contracted malaria—112 *P. vivax* infections, 2 *P. falciparum* and 2 mixed. Ninety six of the benign tertian cases were followed up 74 relapsed. The total number of relapses was 159. The author compares the results of his observations with the 161 cases of induced *P. vivax* malaria reported by JAMES and NICOL in 1932 (quoted from *Discussion* reviewed in this *Bulletin* 1933 v. 30 78). The similarities are striking and confirm James's opinion that there are no great differences between induced and naturally acquired infections. The relapse rate was, however, much higher in the author's cases than in those reported by James. The author believes that tendency to relapse is associated with the massiveness of infection. A multiplicity of infective anopheline bites may result in infection with heterogeneous strains.

A graph shows the number of patients that suffered 1, 2, 3, 4, 5 or 8 relapses. The decline is in the nature of a simple exponential curve, which would also express the chances of the individuals receiving no, one, two, three or more infective bites.

The cases studied indicated that the longevity of *P. vivax* once the parasite has entered the body in its endo- or exo-erythrocytic stages, with or without atelarin treatment, overt or subclinical, lasts one and a-half years and no longer.

Norman Whitt

BIANCO A. A. SAUNDERS, G. M. LEVINE A. S. & CONN R. Long Term Observation of *Plasmodium vivax* Malaria in the Returned Serviceman. Parts II & III. *U.S. Nav. Med. Bull.* 1947 May-June & July Aug. v. 47 Nos. 3 & 4 550-67 753-85 5 figs. [27 refs.]

There is a general impression that *P. vivax* malaria acquired in the South Pacific has a special tendency to relapse over very long periods. Many patients exhibit such a tendency but many others have suffered only one to four relapses during two years, though the place and degree of exposure to infection were identical with those of the group of chronic relapses who suffered up to 20 proved relapses. The future clinical course of malaria appears to be determined by an unknown clinical factor or factors. Repeated relapses have also been known in patients who acquired infection in the Caribbean, Mediterranean and China areas.

In patients observed personally in two or more relapses who had been out of endemic malaria areas and off suppressive mepacrine for more than a year, there was a lengthening of the period between relapses. These patients began to tolerate malaria a great deal better, the attack produced only mild discomfort and responded to very small amounts of antimalaria therapy. Spontaneous remission may occur. But occasionally a severe relapse will occur 3 years after exposure to infection, this is, however, very exceptional.

Numerous expedients were tried to precipitate relapses, all failed. They included erythema doses of ultraviolet light, deep X-ray therapy to the spleen, adrenaline subcutaneously, a course of desoxycorticosterone injections, infusion of 1,000 cc of physiological saline solution via the spleen, diathermy to the spleen for 7 days, immersion in an ice-cold bath to the limit of tolerance, penicillin in maximum dosage, calcium pantothenate, 45 grains daily for 7 days, ketogenic diet with 60 grains of ammonium chloride daily for 7 days, exposure in a pressure chamber, equivalent to 18,000 feet altitude, for five hours, gradually increasing insulin up to 100 units daily, for 14 to 21 days, with periods of hypoglycaemia of 3-4 hours before administration of dextrose, most strenuous exercise.

For treatment, atebirin [mepacrine] is superior to quinine. The officially recommended total dosage, 2.8 gm in 7 days, is effective and nothing is gained by increasing the dose. Where prompt return to duty is imperative, the "flash" treatment may be useful. The patient receives simultaneously 0.4 gm atebirin intramuscularly and 0.2 gm orally, followed by 0.2 gm orally every 4 hours, for 3 doses, a total of 1.2 gm in 12 hours. This is followed by 0.1 gm a day as long as the patient remains in an endemic area, or for 10 to 16 days if on duty in a non-endemic area. This régime compared favourably with the 7-day standard treatment, within 48 hours the patients were ambulatory.

Seventeen patients were treated with plasmoquine-quinine, there was only one relapse during a 120 days' observation period, much the best result obtained with any treatment.

Chronic headache was the most frequent residual symptom which followed treatment of an acute relapse. An extensive electro-encephalographic study was made of these headaches. The qualitative and quantitative electro-encephalogram findings in headaches occurring in chronic recurrent malaria and in headaches unaccompanied by any recognized disease process involving structural changes were almost identical. This indicates that malaria headaches are not an integral part of the malaria infection.

Part III of this paper deals with neuropsychiatric problems in patients suffering from recurrent *vivax* malaria. Psychogenic illness was found to be no different in nature or in frequency in these patients than in a non-malaria group of patients. In each case of mental illness, total personality studies are indicated, malaria is only another incident in the total environment of the personality under study.

MATEO ALONSO, A. Estudios sobre los cuadros clínicos mas graves del paludismo [Clinical Study of the Severer Forms of Malaria] XII Conferencia Sanitaria Panamericana Cuadernos Amarillos Publicaciones de la Comisión Organizadora No 22 Caracas 1946, 74 pp, 3 graphs & 9 figs [Bibliography]

The first part of this article treats of the cerebral forms of malaria. The author's remarks are based on cases which occurred during an epidemic in 1945. In the latter half of the year, 194 cerebral cases were seen, 152 of them first attacks. One hundred and eighty-seven were children between 6 months and 5 years of age, the other seven were respectively 3 of 6 years and one each of

7 9 13 and 20 years. Of the 152 first attacks 84 were in males 68 in females 18 died, 11 boys and 7 girls. A more detailed table of cerebral symptoms shows that of the 194 there were 56 with signs of meningitis, 43 with status epilepticus, 32 with fits of an epileptic type, 28 of coma, 19 with fits apoplectic in type and 18 with symptomatic epilepsy. General remarks are made on these and four cases are detailed. [Attempts have been made to illustrate them by photographs, but all are out of focus and unrevealing.] The last few pages are devoted to discursive remarks on the possible effect of sunlight in the causation of blackwater fever

BOONK, C. Malaria haemorrhagica. [Haemorrhagic Malaria.] *Med. Maandblad Batavia*. 1947 July No. 12, 223-4

The English summary appended to the paper is as follows —

Description of two typical cases of haemorrhagic malaria with severe haemorrhages from the bowel and in one case epistaxis, in the other case haematemesis. Both patients showed a few purpuric haemorrhages into the skin. Large scale blocking by parasite-containing blood corpuscles of capillaries of the intestinal canal as well as of the brain and other organs was present. There were no signs of complicating diseases.

NELSON, M. G. Serological Tests for Syphilis in treated *Plasmodium falciparum* Malaria. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1947 Sept. v. 41 No. 1 127-32.

The author discusses the literature on the false positive serological tests for syphilis which sometimes occur in sera from persons having malaria. These results particularly require recognition in persons suffering concurrently from non-syphilitic, venereal disease and malaria, in whom latent syphilis might be suspected.

At the R.A.F. Hospital, Takoradi, Gold Coast an investigation was made by the author on the sera of 200 Europeans suffering from acute *Plasmodium falciparum* infections. The cases constituted unselected consecutive admissions in all degrees of clinical severity in whom syphilis was excluded by all possible methods. All patients received full anti-malarial treatment upon diagnosis.

Blood was taken within 24 hours of the finding of the parasites and again on the 10th day after the first paroxysm. The sera were tested in parallel against the Ide, Mehncke and Kahn antigens. Positive sera were subjected to the Kahn verification test.

The results of different stages are shown in four tables. False positive results were found in about 3 per cent. of cases, the three tests being in satisfactorily close agreement (Ide 2 per cent., Mehncke 4 per cent., Kahn 3 per cent.). The author refers to the comparable investigation by ELKINS and FIDELAY in 80 patients in West Africa [*Bulletin of Hygiene* 1945 v. 20 254] these workers found 23 false positive results with the Kahn and 4 with the Ide test.

The present author found the Ide test a useful slide method which correlates fairly well with the Kahn reaction. He shows in a table the results of 1,000 sera tested in West Africa against the three antigens in parallel in primary and

treated syphilis, the Weimicke was the most sensitive test and the Ide the least. In the few secondary cases examined, agreement was complete: no non-specific reactions occurred in cases of non-syphilitic venereal disease. The percentages of positive results were, Ide 49, Weimicke 80.4, Kahn 65.4. Discrepant results were found in the sera of 200 healthy Africans examined for evidence of latent yaws or syphilis: the percentages of positive results were, Ide 28, Kahn 37, Weimicke 48.5.

The author considers the Weimicke to be the most sensitive flocculation test under tropical conditions.

False positive results in treated malaria occurred in the first 14 days, and sera were negative, in those followed up, within 40 days of the first paroxysm. The author quotes KITCHEN *et al* [*Bulletin of Hygiene*, 1939, v 14, 619], who found most of the false positives between the 15th and 21st days: the results remained positive for 2 months. He also refers to the work of DAWBER [this *Bulletin*, 1944, v 41, 364]: the optimum time for obtaining false positive results is later in untreated than in treated malaria and the sero-positivity lasts longer.

False positive results due to malaria can be distinguished from true syphilitic reactions by (1) serological follow-up and (2) verification tests. Since malarial false positives only persist for about 1 month in treated cases and 2 months in untreated ones, follow-up for 2 months after full anti-malarial treatment should allow of a differential diagnosis. The author did not find that either the Kahn verification test or the Richardson potentiation test could be relied upon in the tropics to distinguish true from false positive reactions due to malaria.

The author notes the difficulty of achieving serological specificity in areas where yaws is endemic: in any case even where syphilis and yaws can be excluded, certain other factors affect the interpretation of false positive results, of which the following are important:—

- (1) *P. vivax* gives more false positives than *P. falciparum* [KITCHEN, *loc cit*].
- (2) The results vary in the different clinical stages of the disease [KITCHEN, DAWBER, *loc cit*].
- (3) Anti-malarial treatment results in fewer false positives than occur in untreated cases and these results occur earlier (2 weeks) in treated malaria than in untreated cases (3rd week).
- (4) Results on the same sera vary greatly with the test employed: on the whole, the Wassermann reaction is more sensitive to false positive sera in *P. falciparum* malaria and the Kahn test in *P. vivax*.

[For a discussion of false positive tests, see the review of Serum Tests for Syphilis, by T. E. OSMOND, *Bulletin of Hygiene*, 1946, v 21, 627.]

H. J. O'D. Burke-Gaffney

CHINN, M. Nouvelle enquête sur les seroreactions de Bordet-Wassermann et de Kahn dans la malaria. [A New Study of Wassermann and Kahn Reactions in Malaria] *Ann Soc Belge de Méd Trop* 1947, Mar 31, v 27, No 1, 5-15.

The author, working in the Medical Laboratory at Coquilhatville, was prompted to make this study as a result of finding strongly positive WR and Kahn reactions in a European during an acute attack of malaria. Syphilis could be excluded clinically and the patient's serological tests had been negative a few weeks earlier.

After discussing British, American and Belgian workers' views on biological false positive reactions in malaria, the author describes tests made by himself on 265 African children, between the ages of 1 and 13, in whom syphilis could

paludrine (250 mgm. t.i.d.) there was a clearance of the blood parasites in less than 2 days. Pamaquin given alone (0.01 gm. t.i.d.) was followed by parasitaemia for 31 days.

The following changes were observed in the asexual cycle of the parasites with all drugs: (1) slowing down of rate of development of the various stages; (2) tendency of large ring and amoeboid form to "collapse"; (3) bunching together of pigment; and (4) destruction of one or more of the parasite stages in the asexual cycle.

The following changes were attributed to the specific drug taken. *Quinine* had a rapid action. The maximum killing effect seemed to be exerted on merozoites and the youngest trophozoites. *Mepacrine* also had a rapid action. A collapse of amoeboid trophozoites, bunching of pigment and destruction of schizonts occurred. A single dose of 0.2 gm. given by intramuscular injection at the pre-schizont stage usually caused a rapid clearance of parasites and had a lethal effect on the schizonts. *Pamaquine* was a slow-acting drug. It was schizonticidal and active in its effect on merozoites [merozoites are red cells containing merozoites]. Sometimes extrusion of pigment was caused before the parasite matured. The author believes that it is this liberation of pigment which results in the occurrence of a clinical malarial paroxysm. The powerful schizonticidal action of pamaquin is perhaps not widely recognized and it is noteworthy that the daily dosage of the drug (30 mgm.) is 20 to 30 times smaller than that of mepacrine required to produce an equivalent result. *Paludrine* acted on the early schizonts and interfered with chromatin division. The forms which were produced persisted, and resembled female B.T. gametocytes. Paludrine did not clear the blood of benign tertian gametocytes.

Patients were followed up for a minimum period of six months, many of them for longer. In all, 450 cases were followed up. Of every 10 who had relapse infections and were treated with quinine and pamaquin for 10 days, 8-9 were cured. The relapse rate in patients from the Far East treated with 250 mgm. of paludrine plus pamaquin 0.01 gm. t.i.d. were also low though these drugs together proved toxic. In more than 200 patients to whom pamaquin was given at some stage of the illness, the relapse rate was significantly lower than in those to whom other drugs, but no pamaquin, were given. A series of 50 patients with multiple B.T. relapses treated with an intermittent dosage of quinine plus pamaquin over a period of 30 days did not relapse in one single instance.

[This paper reviews the experiences of a team working on infections produced by at least two strains or varieties of *P. vivax*. This is a factor which must always be remembered when various régimes of treatment are compared. In the main, the findings are similar to those of previous workers on this subject. Many of the cases were drawn from a population taking suppressive mepacrine but no indication is given about the regularity of its administration. There is no direct suggestion that the strains in this (Mediterranean) area were resistant to mepacrine. Little support will be found for the assertion that malarial parasites released at schizogony or as the result of treatment is responsible for the relapse paroxysm. The results obtained with the group consisting of returned soldiers of war from the Far East should be considered with reserve as here considerable degree of immunity must have been present. Some of the statements warrant adequate documentation before comment can be made.]

Robert H. Black

DR. M. N. & DUTTA, P. N. A Clinical Study on Paludrine. *Indian Med. Gaz.* 1947 May v 82, No. 5 257-60.

Fifty-eight patients admitted to Medical College Hospital, Calcutta, with active malaria and parasitaemia were treated with paludrine [presumably

orally] Twenty of these had M T infections and the remainder B T , none had recently had any other antimalarial treatment. The blood was examined for parasites every 24 hours. Patients in Group I (4 M T and 8 B T) were given 1 "tablet" [200 mgm] of paludrine thrice daily for 7 days and then twice daily for another 7 days. "Parasites" [presumably asexual] vanished from the blood within from 48 to 96+ hours and the temperature dropped to normal within from 12 to 80 hours in these cases. Group II patients (6 M T and 14 B T) were given 1 "tablet" thrice daily for 7 days. In these cases 'parasites' vanished from the blood in from 24 to 72+ hours and the temperature subsided within from 12 to 96 hours. Group III patients (1 M T and 13 B T) received 1 "tablet" twice daily for 7 days. "Parasites" vanished from the blood in from 24 hours to 72+ hours, and the fever subsided within 24 to 72 hours in all but two cases (both B T) in which it persisted for 120 hours.

Group IV cases were all severe, with very heavy parasitaemia (4 M T and 3 B T). These received 2 "tablets" thrice daily for 2 days, and then 1 "tablet" thrice daily for 5 or 6 days. Those patients who were too ill to swallow the tablets were given them, crushed and suspended in fluid, through a nasal tube. In these cases the "parasites" vanished in from 48 to 72+ hours, and the temperature subsided within 24 to 84 hours.

Group V cases, five in number, were not treated personally by the authors, and received 1 "tablet" thrice daily for 3 days. [No data are given relative to these.]

No toxic effects from the treatment were observed in the 58 cases, and no relapses were encountered within an observation period of 2 to 3 weeks. The authors consider that paludrine is an effective drug and that "so far it appears to hold out fair prospects of being effective against relapse", but [wisely] add that the period of observation is inadequate to justify a final conclusion on this matter.

A R D Adams

CHAUDHURI, R N & RAI CHAUDHURI, M N Clinical Trials of Paludrine.
Indian Med Gaz 1947, May, v 82, No 5, 247-53, 9 figs

Eighty patients (chiefly Indian) admitted to the Carmichael Hospital, Calcutta, suffering from acute malarial attacks of less than a week's duration, who had "fair" or "large" numbers of parasites in their blood, and who had not received antimalarial treatment prior to admission, were treated with paludrine orally. Forty-seven of these had *Plasmodium falciparum*, 30 *P. vivax*, 2 *P. malariae*, and 1 mixed *P. falciparum* and *P. vivax* infections. The dosages employed were as follows —

| Age in years | Above 12 | 6 to 12 | Under 6 |
|--------------|--------------------------------|---|---|
| Regime A | 100 mgm (1 tablet) | 50 mgm ($\frac{1}{2}$ tablet) | 50 mgm ($\frac{1}{2}$ tablet) |
| Regime B | 300 mgm (3 tablets) | 150 mgm (1 $\frac{1}{2}$ tablets) | 100 mgm (1 tablet) |
| Regime C | (1 tablet t d s for 4 days) | ($\frac{1}{2}$ tablet t d s for 4 days) | ($\frac{1}{2}$ tablet b d for 4 days) |

All became afebrile and free from asexual parasites within, at most, 5 days (full data are given in figures, charts and tables).

The average periods within which the temperatures became normal and the asexual parasites disappeared from the peripheral blood after treatment were as follows —

| Regime | Duration of fever | Duration of asexual parasites in blood |
|--------|-------------------|--|
| A | 3 days | 2-6 days |
| B | 3-4 days | 2-4 days |
| C | 2-5 days | 2-3 days |

In those treated under régime A (7 M.T. 2 B.T. 1 Q. and 1 mixed M.T. and B.T. infections) asexual parasites had vanished in 82 per cent. and the temperature had fallen in 73 per cent. of the cases within 3 days. Under régime B (28 M.T. and 16 B.T.) these results were achieved in 88 per cent. and 88 per cent. and under régime C (14 M.T. 12 B.T. and 1 Q.) in 93 per cent. and 89 per cent. respectively.

There was evidence of more rapid action of the drug in *P. falciparum* infections than in those due to *P. vivax*. Gametocytes of neither species were destroyed by the drug, but mosquitoes fed on two patients with gametocytes (*P. falciparum*) 4 or 5 days after treatment did not become infected. The relapse rates in 39 patients (24 M.T. 12 B.T. 2 Q. and 1 mixed M.T. and B.T. infections) observed for 2 to 4 weeks after treatment were high, especially among the cases of M.T. malaria treated with régime A or B. None (8 M.T. 2 B.T. and 1 mixed M.T. and B.T. infections) of the 39 patients treated with régime C relapsed within these periods of observation.

The authors conclude that paludrine has an action on clinical malaria comparable with that of quinine or of mepracrine. A dosage of 100 mgm. of paludrine thrice daily for 4 days is more effective than either a single dose of 100 mgm. or one of 300 mgm. in arresting an acute attack of malaria. No untoward effect was observed in any patient which could be attributed to the drug.

A. R. D. Adams

PATEKH J. G. & BOGHAKI B. P. Clinical Trial of Paludrine in Malaria. *Indian Med. Gaz.* 1947 May v 82, No. 5 253-5.

Fifty patients admitted to the Sir J. J. Group of Hospitals, Bombay, suffering from acute malaria infections were treated with paludrine (presumably orally) after at least one rigor had been observed in each case. These were made up of 26 cases of B.T., 20 of M.T. and 3 of Quartan malaria. There was 1 mixed M.T. and Q. infection.

The dosages of paludrine employed were (1) 100 mgm. (single dose) (2) 300 mgm. (single dose) (3) 100 mgm. daily for from 2 to 8 days (4) 100 mgm. once weekly for from 2 to 24 weeks (5) 100 mgm. thrice daily for from 2 to 10 days and (6) 200 mgm. thrice daily for from 3 to 5 days. In most of the cases treated, even those with a single dose of 100 mgm. (7 B.T. and 3 M.T.) the dosage was effective in arresting the paroxysm usually within 24 hours, but sometimes it took longer (in a case of M.T. getting 100 mgm. weekly asexual parasites persisted for 6 days and the fever for 9 days after the first dose of the drug). Two persons suffering from M.T. malaria died of cerebral complications within 4 hours and 6 hours, respectively, of receiving each a single dose of 300 mgm. of paludrine. In 43 of the 50 persons treated asexual parasites vanished from the peripheral blood, usually in 1 to 3 days after the start of treatment. Gametocytes of all three species, often in increased numbers, persisted in the blood for from 4 to 20 days (and in a case of B.T. infection for 90 days) after treatment. Among 25 patients followed up for 3 weeks to 9 months (15 B.T. 7 M.T. 2 Q. and 1 mixed M.T. and Q.) after the various treatments there were 7 relapses. These occurred in 1 of 3 M.T.

cases treated with a single dose of 100 mgm (these were followed up for at least 4 months), in the only B T case treated with 100 mgm daily for 8 days (followed up for 3½ months), in 4 of 6 B T cases treated with 100 mgm weekly for from 2 to 24 weeks (followed up for from 5 to 9 months), and in 1 of 2 B T cases treated with 100 mgm thrice daily for 3 days (followed up for from 5 to 7 months) Data relative to the dosages, types of infection and subsequent history of the patients are given in a table

Six patients were considered to have shown toxic manifestations due to the drug, but these were unrelated to the size of the dosage, and were attributed to personal idiosyncrasy to the drug The manifestations included weakness and drowsiness, diarrhoea and vomiting, pains in the back and urticarial eruptions with desquamation The authors, on their results, consider paludrine at least equal, if not superior, to other antimalarials in the clinical cure of malaria

A R D Adams

1 BULL U S ARMY MED DEPT 1947, Oct, v 7, No 10, 834-5 **Chloroquine-Diphosphate—a Newly-Standardized Antimalarial Drug**

11 — pp 835-7 **Clinical Evaluation of Chloroquine**

1 Successful results in the United States and elsewhere with the antimalaria drug chloroquine (SN 7618) have already been reported [this *Bulletin*, 1946, v 43, 708, 1011, 1947, v 44, 502, 792] The Medical Department of the U S Army has now adopted this product as a standardized "improved malarial therapeutic and suppressive drug" It is dispensed as tablets of 0.5 gm, equivalent to 0.3 gm of base The nature and effects of the drug have already been described in the abstracts quoted above It is noted that the standard dosage adopted for the initial attack or an acute relapse is one 0.5 gm tablet, followed 4 hours later by a second, this dose of 0.5 gm being repeated at 9 a.m. next morning and at the same time on two further days A total dosage is thus given in 4 days of five 0.5 gm tablets (2.5 gm) containing 1.5 gm. active base This dosage should not be exceeded As a suppressive, a single dose of one 0.5 gm tablet is given weekly

With this schedule, the attack is usually controlled promptly and the parasites removed from the blood in less than 24 hours The interval between relapses is considerably longer than when quinine or mepacrine is used Signs of toxicity are few, mild and rarely require discontinuance of the drug The only troublesome manifestation noted with frequency of any significance was pruritus without rash in less than 10 per cent of patients treated Anorexia, mild nausea and vertigo occurred but were rare The announcement adds that the removal of atabrine [mepacrine] from the list of standard items is not contemplated at present

11 This report records the results of clinical trials of chloroquine on 1,322 patients in U S Army hospitals, under standardized conditions *P. vivax* was present in 1,277, *P. malariae* in 44, and one patient was treated on clinical findings only No *P. falciparum* infections are included Data regarding previous attacks treated with other drugs were available in 896 cases Of these, 90 per cent had suffered from one or more relapses Sixty-five patients had had relapses after previous treatment with chloroquine, 54 of these occurred after a single treatment only In 1,077 patients of whom the relevant data were available, 5 per cent were afebrile on admission, 64.6 per cent became afebrile within 24 hours, 23.7 between 24 and 48 hours and 6.6 per cent after 48 hours In 700 patients, it could be recorded that 59.7 per cent became free of parasites within 24 hours, 29 per cent between 24 and 48 hours, and 8 per cent between 48 and 72 hours The remaining 2.7 per cent did not become parasite-free until after 72 and under 96 hours Of all the 1,322 patients,

21.4 per cent. showed one or more reactions attributable to the drug. Pruritus accounted for 124 of these reactions, anorexia for 86, vertigo or tinnitus for 78, diarrhoea for 33 and urticaria and malaise for 4 and 3 respectively. [Even though they were generally mild and rarely required discontinuance of the drug reactions attributable to the drug to the extent of 21 per cent. do constitute an undesirable feature.]

H J O D Burke-Gaffney

KAMAL, A. M & ARDEL MESSIH, G. Aralen. A New Antimalarial Compound, SN 7618. Reprinted from *J Egyptian Pub. Health Ass.* 1947 Apr 31-6.

The authors record a clinical study of Aralen (the Winthrop Products trade name for chloroquine SN 7618) on similar lines to that previously reported, also from Egypt by HALAWANI *et al.* [this *Bulletin* 1947 v 44 792]. The drug was administered to patients in the Damamhur and Tanta Fever Hospitals in two schedules. The study was confined to new attacks, not relapses. Aralen is supplied in 0.25 gm. tablets. Schedule A consisted of an initial dose of 1 gm. (4 tablets) followed by 0.5 gm. six hours later and again after a further 24 and 48 hours. Thus 2.5 gm. (10 tablets) were given in 3 days.

In Schedule B 2 gm. (8 tablets) were given in equal doses of 0.5 gm every 4 hours.

Forty five patients (39 benign and 6 subtertian infections) were treated on Schedule A. In 35 of the benign cases treatment was given in a morning afebrile period in expectation of an attack. In 22 of them, the attack occurred in the afternoon, but the temperature returned to normal next morning and remained thus until the patients were discharged 12 days later. In 13, the attack was prevented and no subsequent attacks occurred. In the remaining four treatment was given when the temperature was raised. In all, it dropped to normal in 12-24 hours, but a second attack occurred within a further 24 hours. In 33 per cent. of the cases, therefore the normal temperature was maintained, and in all the cases, cure of the acute attack occurred within 24-48 hours.

In the 6 subtertian cases, one patient maintained the initial normal temperature 2 became normal in 24 hours, 2 between 24 and 48 hours and one within 72 hours.

Eight patients with benign tertian malaria were treated on Schedule B. Of these, 4 maintained their initial normal temperatures, 3 became normal in 24 hours and one suffered an attack the next day. Thus, acute clinical attacks were cured within 24 to 48 hours in almost every case whether the drug was given on one or over 3 days. This is considerably shorter than the time required for treatment with quinine or mepacrine.

In a table the authors compare their results with American experience of mepacrine and Aralen which indicate that their own findings in the case of the latter drug in respect of its effect on temperature correspond fairly closely with the American experience [the American experience on which these figures are based is not indicated].

In studying parasite clearance the blood of 28 patients under treatment with Aralen was examined twice daily for 12 days. In benign cases on Schedule B trophozoites and gametes (sic—evidently gametocytes) disappeared from the blood of the 8 patients concerned within 48 hours of treatment. In 15 patients on Schedule A, only 5 were negative in 48 hours, 7 became negative in 72 hours and 3 after 96 hours. Thus only 33 per cent. of patients were free of parasites within 48 hours compared with 96.3 per cent. in the American experience. It is, however emphasized that all the 8 patients on Schedule B became parasite-free in 48 hours.

In subtertian infections (numbers not stated, but presumably 5), trophozoites disappeared within 72-96 hours, but gametes were not affected.

Only 8 patients in the whole series were followed up no relapses were noted at the time of writing (20 to 48 days). There was very little toxicity in this series one patient suffered from headache and one from brief vomiting [Compare with U S Army Medical report above]

H J O'D Burke-Gaffney

SIMEONS, A T W & CHHATRE, K D Preliminary Report on a New Synthetic Antimalarial *Indian Med Gaz* 1947, May, v 82, No 5, 255-7

"Cam-Aqi", 4 (3' diethylaminoethyl 4'-hydroxyanilino)-7-chloroquinoline dihydrochloride dihydrate, is a yellow crystalline powder soluble to the extent of 1 gm in 5 cc of water at 25°C Its structural formula is as follows —

This compound was found by the Parke Davis Research Laboratories to be 'several times as effective as quinine and quinacrine' in "avian malaria", absorption from the gut was very rapid and high plasma levels were rapidly reached [? in birds]. The acute toxicity in laboratory animals was about that of quinacrine [mepacrine], but the chronic was one-quarter to one-half that of mepacrine. Anorexia, vomiting, spasticity, clonic convulsions and respiratory failure were produced only by prolonged dosage several times greater than in the case of mepacrine. The excretion of the drug from laboratory animals was slow.

In view of these observations, viz, its rapid absorption, rapidly achieved high plasma level, slow excretion, low toxicity and therapeutic efficiency "in laboratory animals", the drug was considered suitable for trial in single oral dosage in human malaria, 10 mgm /kilo body weight being the dosages selected.

Fifty men from the Kolhapur State Forces suffering from clinically acute malaria (39 *Plasmodium vivax* and 11 *P. falciparum* infections), most of them with heavy parasitaemia were hospitalized. Two-hourly temperature records were kept for the first 48 hours a tablet of ascorbic acid was given thrice daily as a placebo, a single dose of 'Cam-Aqi' (10 mgm /kilo) was then given by mouth, and the blood was thereafter examined at intervals of $\frac{1}{2}$ to 4 hours as long as parasites persisted in it. In the 39 B T infections asexual parasites vanished from the blood in an average of 25 hours (max. 46 hours) and in the 11 M T infections, 23 hours (max. 40 hours). The fever in both infections subsided within 48 hours. Circulating crescents were not obviously affected, but there was no evidence of further gametocyte formation this is ascribed to the action of the drug on the exoerythrocytic stages of *P. falciparum*. No relapses, clinical or parasitic, were observed among these 50 men over a period of 3 months continuous observation. No toxic effects attributable to the drug were encountered among them, or among a number of non-malarial patients suffering from cirrhosis of the liver, severe anaemia, advanced tuberculosis, nephritis and typhoid, to whom equivalent doses were given.

Sixteen patients (10 *P. vivax* and 6 *P. falciparum* infections) were then treated with 7.5 mgm /kilo, and 18 (8 *P. vivax* and 10 *P. falciparum*) with 5 mgm /kilo of the drug. The results are summarized in the following table —

| Dose mgm./kgm. | Number of cases | | Relapses observed | | Average time required for the | | | |
|-------------------|--------------------|------|----------------------|------|--|------|--------------------------------------|------|
| | | | | | clearance of peripheral blood (in hours) | | temperature to subside (in hours) | |
| | B.T. | M.T. | B.T. | M.T. | B.T. | M.T. | B.T. | M.T. |
| 10 | 39 | 11 | Nd | Nd | 25 | 23 | 28 | 27 |
| 7.5 | 10 | 6 | Nd | 2 | 23.5 | 35 | 25 | 35 |
| 5 | 8 | 10 | 2 | 7 | 32.5 | 33 | 35 | 41 |

From this it is evident that the rapidity of action diminished with the dosage and that relapses occurred increasingly with the lowered dosage, particularly in the M.T. infections. The authors conclude that 7.5 mgm./kilo. is an adequate dosage in B.T. infections, but inadequate in M.T. 5 mgm./kilo. while it arrests the attack, is inadequate to prevent relapse in either infection. A few patients were given 15 mgm./kilo. with enhancement of the rapidity of action in arresting the clinical disease, but this benefit did not appear to offset its increased cost: no evidence of toxicity was noted with the bigger dose.

One hundred and ten children boarding in a Mission School Hostel suffered from much malaria, up to 20 being absent daily with microscopically diagnosed malaria. Every child in the Hostel was given a dose of Cam-Aqi (between 5 and 7.5 mgm./kilo.) within 3 days clinical malaria vanished from the Hostel and remained absent for 2 months, when the children went on holiday. On their return, two had overt malaria, probably relapses, and were treated with 10 mgm./kilo. no further cases occurred over a period of 5 months. Another 116 day boys at the school, with a similarly high malaria incidence, were given 10 mgm./kilo. of the drug: no further cases occurred over 2 months' observation. No toxic effects were seen in any of these children.

For field purposes, where it is impracticable to weigh individuals, the authors suggest the following dosages —

| | | |
|-----------------------------|----------------------|-------------|
| Infants up to 2 years | $\frac{1}{2}$ tablet | 0.1 gm. |
| Children from 3-5 years | 1 | 0.2 gm. |
| Children from 5-14 years | $1\frac{1}{2}$ | 0.3 gm. |
| Average South Indian adults | 2 | 0.4 gm. |
| Tall or heavy adults | 3-4 | 0.6-0.8 gm. |

The authors consider Cam-Aqi a real advance in malaria therapeutics especially for employment in rural population.

[In the Survey on antimalarial drugs 1941-1945 edited by WISNIOLEK (J. W. Edwards, Ann Arbor: Michigan 1946 see this *Bulletin* 1947 v 44 1106) Vol. I, p. 368 and Vol. II, Pt. 2, p. 1165 may be found a description of the similar compound, S.N. 10751 with an account of its chemistry, antimalarial activity in screening tests, mammalian pharmacology and clinical investigation. CHRISTOPHERS, S. R. *Mosquito Repellents. Being a Report of the Work of the Mosquito Repellent Inquiry Cambridge 1943-5.* *J. Hygiene.* 1947 May v 45 No. 2, 178-231 6 figs. [Numerous refs.]

This is a full and well-documented survey of the whole subject of mosquito repellents, and summarizes all previous work, as well as describing the careful experiments carried out in Cambridge during the war. Previous work had been badly standardized, and, frequently impure samples of alleged mosquito

repellents had been used in which small quantities of impurities had been responsible for the effects obtained

The author explains that it is necessary to carry out laboratory tests rather than field tests, to obtain strictly comparable results. He also stresses the importance of having a "standard insect" and gives details of methods of breeding *Aedes aegypti* for that purpose.

The paper contains detailed accounts of experiments with a very large number of different preparations containing substances alleged to repel mosquitoes, and also with a large number of pure substances. Various methods are given for making the anti-mosquito effect last under tropical conditions and when the skin is rubbed. There is an account of the effectiveness of impregnating fabrics with mosquito repellents, and a discussion of the protection given to the skin by closely woven fabrics.

Those concerned with research into the question of mosquito repellents are referred to the original paper which, although it is over 50 pages long, is still a summary of the work, and further condensation is impossible. The practical applications are as follows: Pure dimethyl phthalate is still probably the best repellent for mosquitoes and midges. It should be applied to all the exposed skin in a thin film. Creams containing dimethyl phthalate, several formulae of which are given, give good results, and a little Java citronella incorporated in the cream may keep the mosquitoes at a distance from the skin so that a complete covering is not so necessary.

Finally, the author stresses the fact that there is still much research to be done before a perfect mosquito repellent is discovered, and it should be remembered that different species of insect may react differently to the same chemical substance which may give good protection against one mosquito and little or none against another.

Kenneth Mellanby

NAGENDRA, S. Further Observations on Dry Leaf Packing for the Control of Mosquito Breeding. *Indian J. Malaria* 1947, Mar, v 1, No 1, 67-79

From the results of regular larval catches the author shows that there is much less mosquito breeding in portions of streams controlled by dry-leaf packing than in the sections where canalization is the sole control measure; he attributes this to the creation of a mechanical barrier against oviposition by mosquitoes. No observations were made prior to the institution of control measures, and the anopheline larvae subsequently caught were not identified. R. Ford Tredre

RAO, V. V. & RAMAKRISHNA, V. De-Weeding Tanks and Ponds in Antimalaria Operations. *Indian J. Malaria* 1947, Mar, v 1, No 1, 51-66, 3 figs on 1 pl & 3 text figs

In several areas in India, vector *Anopheles* breed in still water associated with aquatic vegetation such waters may be many acres in extent, rendering their control by chemical larvicides too expensive a proposition for the local villages. The obvious method of control is by removal of weeds, but the authors draw attention to the disadvantages of this, of which the principal is the production of turbidity in previously clear water, rendering it apparently unfit even for domestic purposes coincident with this is the rapid spread of the algal growth, *Microcystis*. To restore the purity of the water, the authors recommend the planting of the common aquatic herb, *Ottelia alismoides*, which inhibits the spread of *Microcystis* and limits the growth of other major plants. Manual removal of weeds may be obviated by (a) the introduction of silt-laden river water, or (b) salinification by saline waters, where these measures are

possible freshwater plants are destroyed in each case. Lastly the authors are enthusiastic about the value of raising vegetable crops on the beds of the tanks when they are dry in the summer months—the soil appears to be rendered sterile for the rest of the year and little aquatic vegetation appears when the tanks refill in the wet season.

BRADLEY G. H. & FRITZ, R. F. Entomological Evaluations of Results of Residual DDT Spraying during 1946. *J. National Malaria Soc.* 1947 June v 6 No. 2, 117-21

In a previous paper [see this *Bulletin*, 1947 v 44 180] the authors describe the highly effective results of residual DDT spraying as observed in some 400,000 homes in the Southern U.S.A., where the spray was applied at the rate of 100 mgm. of DDT per square foot, on one or more occasions. At this time, the authors noted that the effectiveness of DDT deposits as measured by the percentage of sprayed houses found free of live mosquitoes, gradually decreased during successive months following application. However after four months, live mosquitoes were found in only about 8 per cent. of treated houses examined. The present paper describes the continuation of this work in which, during the 1948 season, over 750,000 houses were treated but on this occasion the DDT was increased to 200 mgm. per square foot in an effort to secure a more lasting residual effect and thereby to decrease the frequency of application. A comparison of the results of the two forms of treatment are shown in the following table.

House Inspections on Residual Spray Program

Total treated houses inspected and per cent. free of *A. quadrimaculatus* in afternoon

| Months after spraying | 1948 | | | 1945* |
|-----------------------|-------------------------|--------------------------------|-----------|--|
| | Number houses inspected | Houses free of <i>A. quad.</i> | | Per cent. of houses free of <i>A. quadrimaculatus</i> (for comparison) |
| | | Number | Per cent. | |
| -1 | 6,018 | 5,909 | 98.19 | 98.8 |
| 1-2 | 6,739 | 6,673 | 99.02 | 98.3 |
| 2-3 | 5,321 | 5,271 | 99.06 | 95.7 |
| 3-4 | 2,974 | 2,835 | 98.69 | 94.7 |
| 4+ | 869 | 883 | 98.22 | 94.2 |

| Per cent. | | | 98.00 | 97.2 |

BRADLEY G. H. and ROY F. FRITZ. 1948. Entomological evaluation of DDT residual spraying for malaria control. *Jour. Natl. Malaria Soc.* 5: 141-145.

In later table, the authors show that a greater proportion of sprayed houses found to be mosquito-positive occurred in areas with a high *Anopheles quadrimaculatus* density. During the 1948 period precipitin tests carried out in 25-98 specimens of *A. quadrimaculatus* collected on premises where the houses had been treated with DDT showed that only 40 (0.2 per cent.) gave reactions for human blood, whilst among 8,509 anophelines collected from untreated premises, 74 (1.1 per cent.) gave a similar reaction. Thus, it is indicated that the proportion of the anopheline population that had fed on human beings and survived was 82 per cent. less around sprayed than around unsprayed premises.

[This paper contains a wealth of information packed into a small space, concerning the effectiveness of residual DDT spraying on *Anopheles quadrimaculatus*, and is of particular interest in view of recently published papers by British workers on similar investigations carried out with DDT and directed against *Anopheles gambiae* in West Africa. MURHEAD THOMSON (this *Bulletin*, 1947, v 44, 795) in an important paper has drawn attention to the repellent action exerted by DDT when used as a residual spray against *A. gambiae*, and has shown that although this species is not deterred from entering treated habitations, nevertheless, having fed on human beings, it leaves the house without having taken up sufficient DDT to cause its death. HOCKING (*ibid.*, 879) concludes that in East Africa "*A. gambiae* and *A. funestus* tend to leave a lightly treated building, but that with an impregnation of about 200 mgm per square foot, final mosquito mortality approaching 100 per cent will be achieved, and that on most surfaces the effect will last for at least 4-6 months unless lime is present."

It would appear from these statements, therefore, that in the case of the American vector *A. quadrimaculatus* and of the African vector *A. gambiae*, control by residual DDT spraying will not be fully efficient unless it results in the deposit of not less than 200 mgm DDT per square foot.]

LINK, V B A Preliminary Report on Malaria Control by DDT Residual Spraying *J National Malaria Soc* 1947, June, v 6, No 2, 124-30, 5 figs

It is estimated that during the war over half a million U S troops contracted malaria. A certain unknown proportion of these men have now returned as carriers, and have thereby increased the malaria risk to the rest of the population. So far, there has been no evidence of any interruption of the downward trend of reported cases of indigenous malaria, but in order to combat the possible transmission of malaria from returning Service men, an energetic programme directed primarily against the adult mosquitoes [see BRADLEY & FRITZ, above] has been initiated by the U S Public Health Service and named the "Extended Malaria Control Program" to distinguish it from the "Malaria Control in War Areas Program". The latter programme, which was carried on during the war, had the opposite object, *i.e.*, to protect troops in the United States from acquiring malaria from the civilian population. The author is careful to point out that the effect of the extended programme in accelerating the downward trend of malaria in the U S A is difficult to measure, since the decrease was observed long before the introduction of DDT. The present paper deals with two surveys, one in South Carolina and the other in Porto Rico, in which the author estimated the residual effect of spraying with DDT on the parasite rates in the human population.

(1) *South Carolina* An area adjacent to the Santee Cooper Reservoir was selected. This region was chosen because it represented the "only known high endemic malaria area in the United States. Nearly 20 per cent of the population showed positive blood films in October 1944". A portion of the area adjacent to the reservoir was divided into approximately two equal parts, each having a population of about 1,500 people of whom 90 per cent were negroes. One of the areas was used as a control and the other sprayed with DDT. Before the spraying blood surveys were conducted in October 1944, and in April 1945, while the spraying was carried out in the last two weeks of April 1945 and again during the last two weeks of July 1945. Post-spraying surveys were carried out at monthly intervals beginning in June 1945, and are still being continued. The results of these surveys show that the malaria prevalence in

the unsprayed area rose during the transmission season, but remained at a stationary level in the sprayed area. Apparently no examination was made of the insect vector which in this region is *Anopheles quadrimaculatus*.

(2) *Porto Rico*. Two villages, selected as comparable, were used in this experiment one village being left untreated, while the other was sprayed in November 1944 July 1945 and again in November 1945. Three blood film surveys were made the first in the late autumn of 1944 the second in the spring of 1945 and the third in the late autumn of the same year. The results of these surveys are shown in the following table —

The vector of malaria in Porto Rico is *Anopheles albimanus* which seldom remains within houses except for a few hours during the night. Animal bait traps and light traps, which were used for making collections throughout the year showed that *Anopheles albimanus* was present in sufficient numbers during the study period to transmit malaria, from one to several hundred of these species being collected from all traps during each night. From the results obtained from these two surveys, the author concludes that spraying of homes with DDT decreases the incidence of human malaria.

[In view of the similarly satisfactory results recorded by Bradley and Fritz also members of the Communicable Disease Center when using DDT at a concentration of 200 mgm. per square foot, and basing their conclusions on changes observed in the *A. quadrimaculatus* population it is unfortunate that the author of the present paper has omitted to mention the concentration or method of application of the residual DDT spray responsible for reducing the malaria incidence in the human population. Such information would be particularly interesting in the case of *A. albimanus* whose short indoor resting period presumably reduces its chances of acquiring a lethal dose of DDT.]

BANG, F B, HAIRSTON, N G, MAIER, J & ROBERTS, F H S **DDT Spraying Inside Houses as a means of Malaria Control in New Guinea** *Trans Roy Soc Trop Med & Hyg* 1947, July, v 40, No 6 809-22, 2 charts

This paper describes the reduction in malaria transmission as a result of spraying houses with DDT in a native village, Motu Motu, on the southern coast of Papua, 150 miles west of Port Moresby. A comparable village two miles away was observed as a control. The villages are on swampy land, which is an excellent breeding ground for *A punctulatus moluccensis* [*A punctulatus farauti*] and *A subpictus*. The thatch houses are built on piles 6 to 8 feet above ground. The floors are of rough-hewn planks, laid loosely together, the walls are of woven palm leaf, thatch, or bamboo strips. Adult anophelines may be taken in numbers underneath the houses throughout the night. Though malaria is hyperendemic, mosquito infection rates were very low, anopheline prevalence was, however, extremely high.

All the 126 houses in the experimental village were sprayed in two days. Only the interior of houses was treated, walls, partitions, and the adjoining edge of floor and roof. If the walls were very low, part of the roof was also sprayed. A 4 per cent solution of DDT in kerosene was used at a rate of 100 mgm of DDT per square foot. Four months later, the number of *A punctulatus moluccensis* and *A subpictus* was less than 5 per cent of that found in neighbouring villages. In the control untreated village, there was an increase in both parasite and spleen indexes. In the treated village, the spleen index remained the same and the parasite index was slightly decreased. There was no change in the amount of *P falciparum* infection or of the parasite density in positive smears.

A subpictus was found infected in nature. [It is an important vector in Celebes.] Norman White

JOHNSON, H A & GOODMAN, W L **DDT in Oil as a Mosquito Larvicide** *Pub Health Rep* Wash 1947, Aug 15, v 62, No 33, 1191-8

Oiling to destroy mosquito larvae requires the application of 15 to 30 gallons per acre. Incorporation of DDT very substantially reduces the amount to be applied, and the difficulties of labour and transport. Field experiments in Arkansas were conducted in 1944 and 1946 to explore the new method. The DDT solution in kerosene was applied by means of a hand-atomizer by an operator walking at one or two constant speeds to give between 1 and 3 gallons per acre. A proprietary spreading agent was added at the rate of 0.5 per cent. Results were estimated on dipping counts before and twenty-four hours after treatment. It was observed that, with concentrations of DDT between 0.3 and 1.25, satisfactory kills of larvae of *A quadrimaculatus* were obtained when about 75 gm of DDT were applied per acre. Partial kills were obtained with 50 gm per acre and below. J R Busvine

TARTWELL, C. M. ERICKSON, A. G. BISHOP, E. L. Effects of DDT Mosquito Larviciding on WBDNa. Part I. The Effects on Surface Organisms of the Routine Hand Application of DDT Larvicides for Mosquito Control [TARTWELL]. *Pub. Health Rep. Wash.* 1947 Apr 11 v 62, No. 15 525-54 9 figs. (3 on 2 pls.) Part II. Effects of Routine Airplane Larviciding on Bird and Mammal Populations [ERICKSON] *Ibid.*, Aug. 29 No. 35 1254-62, 4 figs. Part III. The Effects on the Plankton Population of Routine Larviciding with DDT [BISHOP] *Ibid.* 1963-8, 7 figs. (3 on 1 pl.)

These papers are the interim reports of a study undertaken by the U. S. Public Health Service in 1944. Section I represents the first year's work, and Sections II and III that of the second year. There will be a later year's study mainly on the effects on fish.

I. Quantitative sampling of the surface forms, and counts of the surface forms and of dead organisms on the water surface twenty-four hours after treatment, were the methods used for determining the effects of routine treatment with DDT larvicides.

In general, insects were by far the most sensitive organisms. Applications of 0.1 lb. per acre had a fairly substantial effect if repeated as a routine, especially on such large insects as Dytiscidae, Gyrinidae, Hydrophilidae and Corixidae. Even applications of 0.05 and 0.025 lb. per acre had some noticeable effect if they were repeated regularly though none of these rates had any pronounced detrimental action in a single application. DDT dust treatments were less severe than DDT-fuel-oil solutions.

The seasonal effects of routine DDT treatments, as indicated by a comparison of the populations of surface organisms in treated and untreated ponds, were marked. There was an increase in numbers of Oligochaeta, Nematoda and Copepoda and a decrease in insects, especially Chironomidae. Although the forms which increased were very numerous it is unlikely that they compensated in bulk or suitability as fish foods for the decrease in insects.

The direct effect on fishes was early observed to be detrimental at rates of 0.4 lb. per acre or more. Routine treatments at 0.1 lb. per acre caused some fish mortality after 3 to 10 treatments. It would appear to be unsafe to use routine treatments of DDT above 0.05 lb. per acre. This rate is safe except for shallow waters treated, all over repeatedly.

II. The effects of routine (weekly) applications of DDT sprays by aeroplane were observed in 1945 and 1946 at Savannah River Refuge, South Carolina. The DDT larvicide was applied as a thermal aerosol over two large ponds, and as a spray over two more. Observations on ten islands and six dykes were made on the numbers of birds and mammals found active throughout the season.

The results indicated no significant effects in the numbers of birds, cotton rats, house mice, rabbits or raccoons.

III. A special plankton trap and a plankton pump were used to determine the effects of hand applications of DDT larvicide to floating organisms in ponds. The DDT was applied at rates between 0.2 and 0.05 lb. per acre.

The results showed that the effects of DDT were relatively small compared with the variations due to climatic and other ecological factors, and not likely to be important.

KIKUTH, W & MUDROW, Lilly Frühstadien der Vogelmalariaparasiten nach
Sporozoiteninfektion [Early Stages of Bird Malaria Parasites after
Sporozoite Infection] *Klin Woch* 1939, Nov 11, v 18, No 45, 1443-4,
2 figs

In this note, the authors discuss the origin of exoerythrocytic schizonts in bird malaria and point out that up to the time of writing the paper under review there has always existed the possibility that they may have originated from erythrocytic pigmented forms. They now note that in experiments with *Plasmodium calhemerium* the injection of sporozoites into the pectoral muscle was followed by the appearance of a number of uninuclear exoerythrocytic forms and a red nucleus. In addition to these uninuclear forms, two more advanced stages with 2 and 3 nuclei were found. Examination of a bird killed 24 hours after inoculation was negative, but a single uninucleated parasite was found in one killed 40 hours after inoculation. The authors consider that these observations prove that the sporozoite actually develops into non-pigmented exoerythrocytic forms. [This paper, published in 1939, has only recently been received.]

PARAENSE, W L Ação patogênica das formas exoeritrocitárias do *Plasmodium gallinaceum* 1 Investigações preliminares 2 Prova terapêutica da ação patogênica [Pathogenic Action of Exoerythrocytic Forms of *Plasmodium gallinaceum* 1 Preliminary Investigations 2 Therapeutic Test of Pathogenic Action] *Mem Inst Oswaldo Cruz* 1946, v 44, No 1, 147-92, 7 figs, 6 graphs & 4 pls (3 coloured) [21 refs] English summary

When young chicks were inoculated with sporozoites of *Plasmodium gallinaceum* exo-schizonts appeared before erythrocytic forms, since the former are products of sporozoite division. When parasitized blood was inoculated, the first forms to appear were erythrocytic forms. If quinine treatment was given to the chicks following blood inoculation, the chicks died between the 14th and 17th days when it was found that the brain was teeming with exo-schizonts. On the other hand, the blood infection could not be suppressed, as young trophozoites were always present. The control chicks untreated by quinine all died before the 8th day. In another experiment, 80 5-day-old chicks were each inoculated intravenously with 65,000 000 parasites. Death occurred in the untreated controls in 4 to 6 days while in the treated group death occurred in 10-15 days. Exo-forms were present in the brain of the treated group but not in the controls, which showed a massive blood infection. Trophozoites were present in the blood of the treated chicks and these increased in number from the 7th day till the time of death, when there were present about 20 per 100 erythrocytes. When the dose of parasites injected was less than 2,800 per bird, all but two of the treated birds died between the 18th and 21st days. Of untreated birds, two died at the peak of the blood infection and neither showed any exo-infection in the brain. The remaining untreated birds survived this period and died between 21st and 24th days with heavy exo-infection of the brain. It seems evident that the resistance to acute infection in untreated birds was equivalent to the action of quinine in treated birds. In a batch of quinine-treated chicks, examination of the blood and of brain tissue obtained by biopsy was carried out with the object of determining any relationship which might exist between the blood parasites and exo-forms in the brain. The two curves showed a striking parallelism, so that it appears that the increasing trophozoites in the blood of quinine-treated chicks is a direct result of the exo-forms in the brain. In two chicks, recrudescence of parasites occurred 20 days after the beginning of latency. In these chicks there was the

same parallelism between the number of blood trophozoites and exo-forms in the brain. The lack of schizogonic development of the blood trophozoites, beyond suggesting parasitocidal antibodies, appears to indicate that malarial immunity is stimulated by erythrocytic parasites alone as the exo-forms were completing their normal development. In all these experiments, it was not possible to eliminate the blood infection and it remains to be proved whether death is due to the blood form or to the exo-stages in the brain.

An attempt was made to eliminate the blood infection by use of sulphadiazine. Ten 5-day-old chicks were inoculated intravenously and given quinine from the 3rd day. On the 8th day sulphadiazine (1.0 mgm. per kilo of body weight) was given twice daily to 4 of the birds in addition to the quinine. All the quinine-treated birds died between the 14th and 17th days and showed the usual increase of blood trophozoites. The 4 chicks treated with sulphadiazine were examined by brain biopsy on the 4th, 7th and 8th days of treatment. In the brain of all were found damaged exo-forms, while blood smears were negative though the presence of a subpatent infection was demonstrated by blood inoculation to healthy chicks. When treatment was suspended, the blood forms increased and all the birds died with heavy exo-infections. In another experiment, the sulphadiazine was given on two or three occasions with the result that there was a greater survival of the birds treated with sulphadiazine and quinine. The finding of altered exo-forms in the surviving birds is an indication of the rôle the exo-forms play in the death mechanism.

C. M. HAYSON

WILLIAMSON J & LOURIE E. M. Acquired Paludrine-Resistance in *Plasmodium gallinaceum*. I. Development of Resistance to Paludrine and Failure to develop Resistance to certain other Antimalarials. *Ann. Trop. Med. & Parasit.* 1947 Sept. v 41 No. 2, 278-91 [30 refs.]

It was recently shown by BISHOP & BIRKETT and by the present authors [this *Bulletin* 1947 v 44 969-970] that resistance to paludrine which persisted after passage in *Aedes* mosquitoes, could be produced in *P. gallinaceum*. The same strain could not be made resistant to mepacrine, quinine, M 3349 or sulphadiazine. The present paper gives further details of these experiments. With the four last-named drugs, chickens 6- to 8-weeks old were used as hosts and serial inoculation was carried out from one treated bird to another. If the birds survived the course, six daily drug treatments per week were given for two weeks after parasites had been detected in the blood. The survivors, except in the case of those which received sulphadiazine, were generally heavily infected with exoerythrocytic forms. After $\frac{1}{2}$ years of treatment drug-resistance was not detected.

Six-days-old chicks were used as hosts in the production of a paludrine-strain. One series of birds was treated with the minimum effective drug for the normal strain and a second series with the maximum dose by the host. Treatment was started on the day of intravenous inoculation with parasitized red cells and was then continued twice daily for 3 days. In the first series, resistance was established after about 3 months and quit suddenly in the second series it appeared at approximately the same time as a result, it is believed, of mutation. About 20-40 times as much drug was tolerated by the resistant strains of parasites as by the normal without apparent change in morphology. The resistance to paludrine did not extend to other drugs, except the N_6 -methyl derivative. The possible mechanism of production of drug resistance and its significance in the treatment of human malaria with this drug are discussed.

J. D. FULLON

MARSHALL, P B Mode of Action of "Paludrine" [Correspondence] *Nature* 1947, Oct 4, 463

HAWKING [this *Bulletin*, 1947, v 44, 648] has given evidence that paludrine is inactive against malarial parasites *in vitro*, but becomes active after it has undergone some metabolic change in the body. In contrast, Marshall finds that paludrine 1/60,000 produces a greater inhibition of oxygen consumption of *P. gallinaceum* in the presence of glucose or lactate than does quinine 1/6,000. Inhibition of oxygen consumption by paludrine is essentially different from that by iodo-acetic acid. The author suggests that paludrine exerts its ant-malarial action, at least partially, by inhibiting the oxidation processes of the malaria parasite, but not the anaerobic breakdown of glucose to lactic acid. However, the concentrations required to produce these effects are higher than those occurring in therapy or those used by Hawking, so their significance is not yet certain.

RIGDON, R H An in Vitro Study of the Mechanism producing Rapid Diminution in the Parasitemia in Ducks infected with *Plasmodium lophurae* *Amer J Hyg* 1947, Sept, v 46, No 2, 254-9, 3 figs

Oxygen, nitrogen, and carbon dioxide are bubbled for two hours through citrated blood obtained from ducks infected with *P. lophurae*. The blood is then inoculated into clean ducklings and the degree of parasitaemia is measured in the ensuing infections, the results being compared with an injection of untreated blood as a control. Treatment with carbon dioxide resulted in a lesser degree of parasitaemia than did that with nitrogen or oxygen. The author suggests that the accumulation of CO₂ in the body at the peak of the infection may be the cause of the sudden drop in numbers of parasites following the crisis.

[So many different factors are involved that it is difficult to conclude much from these experiments. The author states in the discussion that one should be careful in assuming that CO₂ is lethal for the plasmodia, and yet in the summary says that "apparently the plasmodia are killed by the CO₂"]

THOMSON, K J, FREUND, J, SOMMER Harriet E & WALTER, Annabel W Immunization of Ducks against Malaria by means of Killed Parasites with or without Adjuvants *Amer J Trop Med* 1947, Mar, v 27, No 2, 79-105, 15 figs & 1 pl

In a previous paper, the authors have referred to experiments showing that it is possible to immunize ducks against *Plasmodium lophurae* with a vaccine consisting of formalin-killed parasites combined with paraffin oil containing killed tubercle bacilli and an emulsifying agent [this *Bulletin*, 1946, v 43, 311]. In the present paper further details are given. It is possible to immunize adult ducks against infection with *P. lophurae* and *P. cathemerium* by injection of the vaccine. With *P. lophurae* immunity is revealed by prevention of death or by lowering the degree or shortening the duration of parasitaemia and with *P. cathemerium* by modifying the course of parasitaemia. Repeated intramuscular injections protect adult ducks for six months, but single injections with multiple sites protect to a less extent. If the injections are given into the subcutaneous fat and not into the muscle no protection results. In ducks, the inclusion of killed tubercle bacilli in the vaccine gave rise to amyloidosis of the liver and spleen, but this did not influence the immunity in any way. In monkeys immunized against *P. knowlesi* by vaccine containing killed tubercle bacilli amyloidosis did not occur.

RIVERO M. D. La infección experimental por el *Haemoproteus columbas* Celli y Sanfelice. [Experimental Infection with *H. columbas*.] *Medicina*. Mexico. 1947 May 10 v 27 No. 531 197 204 9 figs.

Two views exist as to the method of transmission of *Haemoproteus columbas* from pigeon to pigeon. According to ARAGÃO species of *Lyachia* infect themselves by taking up blood from an infected bird. In the intestine, flagellation of the male gametocyte occurs and the fertilized female becomes an ookinete. This discards its pigment and as such is inoculated to the pigeon. According to ADIE the ookinete in the intestine of the *Lyachia* penetrates the wall of the stomach and develops into an oöcyst, giving rise to sporozoites which invade the salivary glands.

In order to test these views, the author has followed the development of the parasite in larvae of *Triatoma*. This proceeds as far as the formation of ookinetes but no further. With the contents of the stomach of triatomas 4-48 and 72 hours after feeding on an infected pigeon, uninfected pigeons were inoculated intravenously. From the 12th to the 20th days after the inoculation the blood showed invasion by young gametocytes which during the following two months developed into mature forms. It is evident that the ookinetes are able to start an infection as ARAGÃO had maintained. [See also this *Bulletin* 1941 v 38, 568.]

TRYPANOSOMIASIS

FAIRBAIRN H. The Infection of Rats by Trypanosomes (*T. rhodesensis*) taken from Man early in the Disease. *Ann. Trop. Med. & Parasit.* 1947 Sept. v 41 No. 2 218-25 1 fig.

In this work the author has continued to study the relation between the electric charge carried by trypanosomes and the results obtained in experimental trypanosomiasis [see this *Bulletin* 1947 44 649]. A single strain of *Trypanosoma rhodesense* (isolated in 1934 from a human case) was used, but "lines" of the strain had been maintained in sheep Thomson's gazelle, and monkey by cyclical transmission through *Glossina morsitans*.

Tsetse flies infected with one or other of these "lines" were allowed to bite human volunteers. Fluid from the site of the bite was examined daily and, when trypanosomes first appeared, blood from that site was used to inoculate rats and to prepare films for studying the morphology of the trypanosomes. In the same way when trypanosomes showed in ordinary blood films venous blood was taken for blood films and for rat inoculations.

Four types of results were obtained in the rat experiments. In Group I all rats became infected after the usual incubation period of 4-8 days. In Group II all rats became infected after an increased period of incubation (9-18 days). In Group III some rats were infected after incubation periods varying from 8-50 days and others remained uninfected. In Group IV all rats remained healthy.

The length distributions of the 6 types of trypanosome recognized by the author (long intermediate, short, each either positively or negatively charged) were determined from the blood films. All types were present in each group though in different proportions, but only the long type need be considered. By the author's hypothesis the other types cannot initiate infection (for which both the positively and negatively charged forms of the long type are required). From previous observations, the normal mean length for the positive form of *T. rhodesense* is 29 μ and for the negative form 28 μ . In Group I a considerable

proportion of individuals had lengths greater than the general mean in Groups II, III and IV the proportion was progressively less. Relating this finding to the result of the rat experiments, the author suggests that trypanosomes whose length is above the mean are "mature". They alone can enter into syngamy and produce infection. [The author and his co-worker CULWICK are putting forward new concepts on trypanosomiasis, so it is their duty to plan their experiments in such a manner that the results provide unequivocal evidence for or against their hypothesis. The experiments detailed in this communication fail, in the reviewer's opinion, to achieve this end. Why is it important to test the virulence to rats of the trypanosomes on their first appearance in the blood? No reason is advanced. No consideration is given to the author's discussion of his results to an apparent relation between the "line" of the trypanosome and its virulence to rats. For instance, Table I shows that of 144 sheep-line-man-rat tests 65 (95 per cent) were positive, whereas of 69 monkey-line-man-rat tests 51 (35 per cent) were positive. The fact is noted that no comment is made. Then when dealing with syngamy of the long forms, the statement is made that the argument does not apply to syringe-passage strains which consist only of long forms, although their mean length is reduced. Inoculation of a single trypanosome of these strains will produce infection, and this is taken to mean that genetic segregation has taken place, since conjugation to produce short and intermediate forms cannot occur. Surely this is assuming the correctness of the hypothesis which the experiments are supposed to be testing.]

VANDERPLANK, F L. Experiments in the Hybridisation of Tsetse-Flies (*Glossina*, *Diptera*) and the possibility of a New Method of Control. With Appendix I by W H PORRIS. Trans Roy Entom Soc London 1947, June 30, v 98, Pt 1, 1-18, 8 figs on 2 pls [12 refs]

The author writes about what would perhaps be better described as "cross-pairing" rather than "hybridisation" between two closely related species of tsetse *G. morsitans* and *swynnertonii*.

The virgin female tsetse is attractive to the male very early in life and pairing takes place either before or very soon after the first meal. The author finds that if both sexes of these two species are kept together in a cage, mating is random. That is to say, the number of matings with an individual of the same and of the other species is determined by abundance, and there is no "preference" for a partner of the same species.

When pairing takes place, either with a male of the same or of the opposite species, the female is generally, though not always, inseminated. If the pairing has been with a male of the other species she is in effect sterilized, for she ovulates in a normal way but the eggs fail to hatch. As a somewhat rare event the egg will hatch and eventually give rise to a normal pupa. The hybrid that emerges from such a pupa resembles *G. swynnertonii* in its external characters whichever species may have supplied the mother. In the case of a male hybrid, it is found that the genitalia exhibit intermediate characters, no similar differences can be shown in females which are in any event indistinguishable in these closely related species. The hybrids are themselves sterile.

The author shows that in nature the two species overlap in certain areas, in which a few males with intermediate genitalia occur. As such individuals are never found except where the two species are present, one is justified in regarding them as hybrids. He also shows that if large numbers of *morsitans* are introduced into an area inhabited solely by *swynnertonii*, cross-pairing

RIVERO M. D. La infección experimental por el *Haemoproteus columbae* Celli y Sanfeliu. [Experimental Infection with *H. columbae*.] *Medicina*. Mexico. 1947 May 10 v 27 No. 531 197-204 9 figs.

Two views exist as to the method of transmission of *Haemoproteus columbae* from pigeon to pigeon. According to ARAGÃO species of *Lynchia* infect themselves by taking up blood from an infected bird. In the intestine, flagellation of the male gametocyte occurs and the fertilized female becomes an ookinete. This discards its pigment and as such is inoculated to the pigeon. According to ADIX the ookinete in the intestine of the *Lynchia* penetrates the wall of the stomach and develops into an oocyst, giving rise to sporozoites which invade the salivary glands.

VANDERPLANK, F L Experiments in the Hybridisation of Tsetse-Flies (*Glossina*, *Diptera*) and the possibility of a New Method of Control With Appendix I by W H POTTS *Trans Roy Entom Soc London* 1947, June 30, v 98, Pt 1, 1-18, 8 figs on 2 pls [12 refs]

The author writes about what would perhaps be better described as "cross-pairing" rather than "hybridisation" between two closely related species of tsetse *G. morsitans* and *swynnertoni*.

The virgin female tsetse is attractive to the male very early in life and pairing takes place either before or very soon after the first meal. After pairing the female ceases to be attractive to the male for the rest of her life. The author finds that if both sexes of these two species are kept together in a cage, mating is random—that is to say, the number of matings with an individual of the same and of the other species is determined by abundance, and there is no "preference" for a partner of the same species.

When pairing takes place, either with a male of the same or of the opposite species, the female is generally, though not always, inseminated. If the pairing has been with a male of the other species, she is in effect sterilized, for she ovulates in a normal way but the eggs fail to hatch—as a somewhat rare event the egg will hatch and eventually give rise to a normal pupa. The hybrid that emerges from such a pupa resembles *G. swynnertoni* in its external characters, whichever species may have supplied the mother. In the case of a male hybrid, it is found that the genitalia exhibit intermediate characters; no similar differences can be shown in females, which are in any event indistinguishable in these closely related species. The hybrids are themselves sterile.

The author shows that in nature the two species overlap in certain areas, in which a few males with intermediate genitalia occur. As such individuals are never found except where the two species are present, one is justified in regarding them as hybrids. He also shows that if large numbers of *morsitans* are introduced into an area inhabited solely by *swynnertoni* cross-pairing

occurs and occasional hybrids are produced. It is likely therefore on the basis of the laboratory work, that many other females have been inseminated by the male of the introduced species and are thereby sterilized (though this is not actually demonstrated). The method might perhaps be used to attack a species in nature, especially if the numbers have been brought to a very low level by some other method. The method could only be employed where the introduced species would be able to live in the environment in which it is liberated but could probably not occupy it permanently. P. A. Buxton

NATURE, 1947 Oct. 11 485-8. D.D.T. and the Aeroplane in the Control of the Tsetse Fly and Trypanosomiasis in South Africa.

The note describes a meeting in London in September 1947 at which Dr P. J. DU TOIT discussed recent South African work against tsetse and showed a film.

The particular problem was the control of *Glossina pallidipes* in a small game reserve in Zululand. In the most recent work, an attempt is made to control this insect by DDT smoke obtained by discharging a concentrated solution into the hot exhausts of aircraft, and sublimating the insecticide, which then falls and is found to penetrate dense bush. The smoke was put down by Anson aircraft flying cross wind at 120 m.p.h. the effective swath was 70 yards at wind speeds of about 8-10 m.p.h. At any one moment a large proportion of the tsetse population is in the pupal stage in the soil the smoke was therefore put down on six occasions over a period of weeks. The cost of insecticide for six occasions is given as 12s. per acre, and the cost of aircraft services as 6s. [which is surely a token figure].

In broken ground, with ravines, where low flying would be exceptionally difficult, DDT smoke may be produced by small generators placed by ground party.

The catches after spraying were exceedingly low but no figure is given. Harris traps have in years past also made an enormous reduction in the same insect in the same area, but never exterminated it. [The speaker was, it seems, rather optimistic: he hoped that a very great mortality having been produced, nature would step in and do the rest.] P. A. Buxton

- i. DODD M. C. The Chemotherapeutic Properties of 5-Nitro-2-Furaldehyde Semicarbazones (Furacin). Reprinted from *J. Pharm. & Exp. Therap.* 1946 Apr. v 86 No. 4 311-23. [10 refs.]
- ii. KRANTZ, J. C. Jr & EVANS W. E. Jr. A Contribution to the Pharmacology of 5-Nitro-2-Furaldehyde Semicarbazones. *Ibid.* 1945 Dec. v 85 No. 4 324-31 1 chart.

L. It has been found that a nitro group in the 5-position confers definite antibacterial properties on a variety of 2-substituted derivatives of furane. The most promising of an extensive series examined was 5-nitro-2-furaldehyde semicarbazone ("Furacin") —

"Furacin" is active not only against a wide range of bacteria *in vitro* and *in vivo* but also against *Trypanosoma equiperdum* infections. Its activity against bacteria embraces both Gram-positive and Gram-negative organisms.

as well as *Mycobacterium tuberculosis*, but it is conspicuously without effect against *Ps. pyocyanea*, and is only very slightly active against *Str. viridans* and *Str. pneumoniae*.

The compound is only slightly soluble in water (1/4,200), and for therapeutic tests, carried out in mice and rats, it was administered as a suspension in 10 per cent gum acacia, by stomach tube, or in 10-20 per cent gum acacia subcutaneously or intravenously. Details are given of successful results in infections with two Gram-positive bacterial species (*Staph. aureus* and *Str. haemolyticus*) and two Gram-negative species (*Salm. paratyphi B* and *Salm. typhi-murium*).

There was a fairly high degree of activity against *T. equiperdum* infections, the following therapeutic indices being given, where treatment was by stomach tube—For mice LD50/CD50, 9. For rats, LD100/CD100, 8.

Histological examination of organs from animals sacrificed after oral treatment with maximal dosages failed to reveal the pathological basis for the drug's toxic action at high dosage-levels. However, maximal subcutaneous doses gave rise to severe hepatitis and extensive degeneration of the tubular epithelium of the kidney.

[There is an important gap in the data on this compound's performance against *T. equiperdum* infections. The tests against bacterial infections generally showed the curious feature that a dose of about 150 mgm per kgm orally produced the maximal therapeutic effect, whilst larger doses—though still well below the lethal range—gave significantly poorer results. For example, in *Staph. aureus* infections in mice survival-rates after dosages of 150, 200 and 250 mgm/kgm were 63.3, 36.7, and 40.0 per cent respectively, again, in *Salm. paratyphi B* infections the rates were 58.3, 61.7 and 33.3 per cent respectively. Deaths after treatment by the highest dose were the result of infection and not of toxic action of the drug. In the protocols given for tests against *T. equiperdum* infections, however, no results are recorded for doses higher than 150 mgm/kgm for mice and 100 mgm/kgm for rats.]

Standard pharmacological and biochemical techniques were employed in order to determine the toxic potentialities of "Furacin". The observations included studies of the effects of the compound on blood pressure, respiration, and the heart-beat as shown by electrocardiogram and by direct observation during perfusion or after extirpation. The effects on cytochrome oxidase and tissue dehydrogenase activity were also studied. Acute and chronic toxicity tests in rats, mice and monkeys were supplemented by blood counts and histopathological studies on the organs of animals which had received the highest dosages.

These tests revealed a very low degree of toxicity. Several persons were given 100 mgm orally three times a day, without symptoms being produced. The dose was increased to 2-4 gm daily which resulted in nausea in 20 per cent of cases. There were no changes in the blood or urine of these persons [The numbers treated are not stated]. [See also *Bulletin of Hygiene*, 1946, v 21, 614.]

PINTO C. Epidemiologia da doença de Carlos Chagas no Estado do Rio Grande do Sul—Brasil [Epidemiology of Chagas's Disease in the State of Rio Grande do Sul, Brazil]. *Mem. Inst. Oswaldo Cruz* 1946, June, v 44, No 2, 363-400, 26 figs. (3 maps).

After briefly describing the physiographical features of the State, the author relates that Sanitation Posts have been established in 78 of the 92 municipal districts and that during the 8 years, 1939-46, 73 cases of Chagas's disease have been observed, the largest number in any single year was 27 in 1942. *Triatoma infestans* is the vector. *Eutriatoma rubrovaria* is found in the burrows of the

armadillo *Dasypus hybridus* in the open fields during the winter in temperatures about zero Centigrade. Of the total cases 48 were in children (52 in adults in 3 the age was not known. Forty-seven were acute, of whom 38 were children, 7 adults, 2 not known and of 25 chronic cases (this makes a total of 72 only) 11 were children and 14 adults. As regards nationality 38 were whites, 4 negroes, 3 mulattos, but as many as 28 were not known. In all the acute cases Romana's sign was present and in 13 there was some cardiac disturbance—tachycardia, arrhythmia, extra-systoles or signs of myocarditis. Diagnosis was made either by direct blood examination or by xenodiagnostic methods. Details as to nationality, age, sex, clinical characters, etc. are given for each patient in a table. The houses were infested with *Triatoma* and these were often found collected under the mattresses in the cold weather.

The article contains several maps of the district, photographs of the country and meteorological and epidemiological details in graphs.

MUNIZ, J. Do valor da reação de precipitina no diagnóstico das formas agudas e sub-agudas da Doença de Chagas ("Trypanosomiasis Americana") [A Precipitin Reaction in Diagnosis of Acute and Subacute Forms of Chagas's Disease.] *Brazil-Médico*. 1947 July 19 & 28 v. 61 Nos. 29/30 281-7 1 graph & 1 fig. English summary

The author with his colleague DE FREITAS, has previously published articles dealing with immunity reactions in Chagas's disease [see this *Bulletin* 1945 v. 42 875 1947 v. 44 571] complement fixation and agglutination. In the present paper he describes a precipitin reaction. The method of obtaining the extract is very detailed and those interested must consult the original. Suffice it here to say that, by employing Fuller's method, he obtained from cultures of *T. cruzi* a stable, water-soluble fraction. A very small quantity of serum is needed and the results seem, in the author's hands at least to be very satisfactory. 0.1 cc. of serum (which must be quite clear and free from blood) of the suspected patient is placed in a small tube of 3 mm. diameter. An equal quantity of precipitinogen is added down the wall of the tube to form a layer over the serum. A control with physiological saline is put up at the same time. The tubes are left at room temperature. In strongly positive cases a disk appears at the surface of contact in 1-2 minutes (4 plus). Less acute cases give the reaction in 10-20 minutes (3 plus) or even longer after half an hour (2 plus). In a table are given details of 21 cases, stating the length of interval since infection occurred, the results of the precipitin test and the agglutinating titre of the serum. The ages of the patients ranged between 7 months and 14 years. In most, the tests were made more than once at intervals up to 178 days after the date of infection. Adding these cases of acute disease to 12 previously noted the author states that in every one of the 33 the reaction was positive in the early weeks of infection and remained so for periods up to 4 months. The test is, therefore, of special value in the early stage before definite symptoms appear and takes less time than search for trypanosomes in the blood, and a positive result is not given by leishmaniasis patients (though immune sera prepared against leishmanial diseases do react). The reaction is of some quantitative value because it occurs as a rule when the agglutination

titre is 1 500 or over It has little value in chronic cases, only 18 per cent of more than 200 such patients gave a positive For these chronic cases, other methods, such as complement fixation or venodiagnosis, are better

MUNIZ, J, NOBREGA, G & DA CUNHA, M Ensaio de vacinação preventiva e curativa nas infecções pelo *Schizotrypanum cruzi* [Attempts to vaccinate against *T cruzi* Infections] *Mem Inst Oswaldo Cruz* 1946, Sept, v 44, No 3, 529-41 English summary

Though the results were on the whole negative, this investigation was one of interest It is known that inoculation of cultures of *T cruzi* into rabbits results in the formation of specific antibodies, their serum agglutinating in titres up to 1 50,000 The authors have utilized Rhesus monkeys, *Macaca mulatta*, because infection of *T cruzi* in them evolves very like that in man They tested the value of the vaccine (killed by merthiolate 1 10,000) prophylactically and curatively after infection, inoculation was made intradermally, subcutaneously, intramuscularly and intravenously The details are given minutely in a series of protocols and described in the text Those interested should study the original, suffice it here to repeat what has been said above that the vaccine proved neither protective nor curative in doses of 24-28 mgm

DE BARROS, O M & ROSENFELD, G Leishmaniose visceral Americana Novo caso [A New Case of American Visceral Leishmaniasis] Reprinted from *Rev Clin São Paulo* 1944, v 15, No 4, 97-102, 5 figs (3 on 1 pl.)

KATZENELLENBOGEN, I Cutaneous Leishmaniasis in Palestine with a Report of a New Endemic Focus in the Negev *Harefuah*, Jerusalem 1947, Sept 14, v 33, No 6 [In Hebrew 98-100 (17 refs) English summary 100]

Revivim-Asluj, in the Negev, is a new Jewish settlement in Palestine with "sand-desert" conditions There are some 30 settlers there, and between September 1946 and January 1947, 25 of them developed oriental sores of a "dry" type after a residence of 1 to 2 years The sores also occur in nomad Bedouin in the neighbourhood of Revivim, but are absent in the case of settlers and nomad Arabs in other parts of the Negev

The salinity of the soil is high (0.25 to 1.0 per cent.) huge open reservoirs for rain water were built recently and there is a large cave in the settlement, which has been used as a "rest house" by nomads for centuries. Thus, conditions in Revivim favour the breeding of sandflies.

It is not considered that the spread of oriental sore in Palestine can be attributed to carriers from the Dead Sea area or from neighbouring countries, but it is presumed that latent foci of leishmaniasis-infected sandflies exist and that Revivim is one. Outbreaks of cutaneous leishmaniasis occur in Arabs and Jews alike when non-immune persons enter the area, as has already occurred in the Dead Sea.

HAMPTON J W F. The Excretion of Stilbamidine and some related Compounds in Experimental Animals. *Aus. Trop. Med. & Parasit.* 1947 Sept., v 41 No. 2, 228-33. [16 refs.]

Studies on the excretion of stilbamidine by human subjects have previously been reported in this Bulletin [1943 v 40, 122 1945 v 42, 18] as well as similar investigations on laboratory animals (*ibid* 1946 v 43, 723). In the present paper the excretion of this substance and of a hydroxy amino- and iodo-derivative in the urine of rats and rabbits has been investigated after single or repeated doses. Stilbamidine itself was estimated by a modification of the fluorescent method of HENRY & GRIMLEY (this Bulletin 1943 v 40 122) and also by the glyoxal method of FULLER (this Bulletin 1945 v 42, 264) after extraction of the bases from urine in butyl alcohol. Amino-stilbamidine was estimated by fluorimetric and diazotization procedures, iodo-stilbamidine colorimetrically and the hydroxy-derivative by the yellow colour of the base after its extraction by butyl alcohol other methods having proved unsuitable.

After a single intravenous injection of stilbamidine only about 1 per cent. of the administered dose was recovered in fluorescent form about twice this amount was recovered after repeated dosage. When the dose injected was small, excretion could not be detected till 5 doses had been given after 10 doses there was a sudden rise in the amount present in urine, suggesting that storage had been taking place in the body. The curious observation was made that "proportionately very much less of the compound was excreted by the animals receiving large doses than by those receiving small doses, when the reverse was expected."

The results of colorimetric estimation of stilbamidine indicated an excretion 20 times greater than that found by the fluorimetric method. In the case of amino-stilbamidine, higher results for excretion were obtained by the diazotization than by the fluorimetric method. Stilbamidine thus appears to be excreted largely in the form of a non-fluorescent (compound) the identity of which was not established. [When discussing the reason for the low excretion values found for stilbamidine by the fluorimetric method of estimation, the author incorrectly attributes to the reviewer the view that the addition of water occurs at the ethylenic linkage in stilbamidine when its solutions are exposed to light. Recently FULTON & DUNN (this Bulletin 1947 v 44 838), have shown by X-ray crystallographic methods that dimerization occurs with the formation of a cyclobutane derivative.]

THOMPSON, R H S & WHITTAKER, V P Antidotal Activity of British Anti-Lewisite against Compounds of Antimony, Gold and Mercury
Biochem J 1947, v 41, No 3, 342-6, 1 fig [20 refs] [Summary appears also in *Bulletin of Hygiene*]

BAL protects the isolated pyruvate oxidase system of pigeon brain from poisoning by compounds of antimony, gold and mercury. Its antidotal potentialities *in vivo* may therefore be inferred. The compounds examined were — Antimony Tartar emetic, "Stibophen", and "Stibacetin". Gold Gold chloride, "Myocrisin", and 1, aurothioglucose. Mercury Mercuric chloride. [For other references to BAL in arsenical intoxication see *Bulletin of Hygiene*, 1946, v 21, 658, 737, 864, 1947, v 22, 189, 511] E M Lounie

FEVERS OF THE TYPHUS GROUP

MACKENZIE, M Typhus Fever in England *Bull Office Internat d'Hyg Publique* 1946, Oct -Nov -Dec, v 38, Nos 10-11-12, 873-4 [French version 871-2]

Typhus fever is now rare in England and Wales, but during the war years special precautions against its importation became necessary. These included the provision of a panel of expert consultants, the selection of isolation hospitals as special centres, arrangements for disinfection of homes and contacts, the formation of special sanitary teams, provision of facilities for immunization of exposed medical and sanitary workers, the supplying of DDT and sprays to Local Authorities and the issue of a memorandum on louse-borne typhus fever.

Two types of yolk-sac vaccine were provided, one (Cox type) prepared by the U S Public Health Service and the other by the Connaught Laboratories, Toronto. Facilities were provided for the inoculation of authorized travellers abroad.

During the war, until 1944, only two suspected cases of typhus were reported in England and Wales. One was probably of the tick-borne type and therefore of no local epidemiological importance. The other was in a soldier who became ill a few days after an anti-typhus inoculation. In this case, the diagnosis was not confirmed as a result of serological tests.

The danger increased after the invasion of Germany and VE day, especially as regards the risk of infection being carried by returning prisoners of war. In fact, 21 such cases were imported, 14 in ex-prisoners of war and 7 in medical students returning from voluntary duty in Belsen. Measures taken to prevent secondary cases were successful and none occurred thereafter.

H J O'D Burke-Gaffney

BOYER, J Epidemiological Study of Cases of Typhus Fever found in the Paris Area on the Return of Prisoners and Deportees *Bull Office Internat d'Hyg Publique* 1946, Oct -Nov -Dec, v 38, Nos. 10-11-12, 865-70 [French version 855-64, 5 graphs]

Among prisoners and deportees who returned to France in 1945, there were 167 cases of typhus fever in Paris, which was the main centre for dealing with repatriated persons. There were only 15 secondary cases among persons who came in contact with the patients after their return to Paris. In four of the

secondary cases, the only contact had been with repatriated persons who had never suffered from fever and who, therefore, were assumed to have suffered from "inapparent" attacks of the disease.

Plans had already been made for prompt diagnosis of cases and for the disinfection and disinfection of all contacts, who were kept under close observation for 25 days instead of the 12-day period prescribed by international regulations. Contacts were not vaccinated because they ceased to incur risk of infection after detection, but nurses, doctors, and officials of the Repatriation Service were vaccinated with the Durand and Giroud vaccine. Only one vaccinated person was attacked, and she made a good recovery.

DIAS, A. de C. Typhus Fever in Portugal during the War Years. *Bull. Office Internat. d'Hyg. Publique*. 1948, Oct.-Nov.-Dec. v 38, Nos. 10-11-12, 878-80 [French version 875-7]

The influx of war refugees and the partial mobilization of Portuguese troops throughout the Portuguese empire exposed Portugal to a number of infectious diseases of these, typhus in particular was a serious risk, because of the great epidemic in Spain in 1941-42, which demanded stringent precautions along a wide stretch of the frontier. Indeed, of 50 cases which did occur in Portugal in 1941 more than half were traceable to the Spanish epidemic. It was proved that the disease was imported by gypsies, even in the city of Lisbon where typhus has always been rare.

Figures are given of incidence and deaths by ages, in Lisbon and the provinces, between which the cases and deaths were exactly evenly divided (25 and 3 in each respectively). It is noted that in Lisbon, none of the 3 deaths occurred in people over 50, when the severity is greater in the provinces, 1 death occurred in a person over 50 and 2 in persons of unknown ages.

Cases also occurred in Portugal in 1943 and 1944. In two districts, one coastal and one inland, which were formerly the seats of epidemics. Two small epidemic centres appeared in the northern areas in 1943 and in 1944 epidemics occurred in two other northern and one south coastal area. The last comprised 19 cases only and it would have been the most serious but for prompt measures taken, since the commune concerned (Othad) is a populous fishing and fish-canning centre.

The incidence and mortality of typhus in Portugal during the war years is shown in the following table —

| Year | Cases | Deaths |
|------------------------------|-------|--------|
| 1939 | 33 | 10 |
| 1940 | 6 | 6 |
| 1941 | 50 | 8 |
| 1942 | 18 | 14 |
| 1943 | 57 | 5 |
| 1944 | 124 | 21 |
| Yearly averages 1929-1938 | 48.1 | 12.5 |

It is noted that unusually high death rates are recorded in 1940 and 1942, but the author attributes the low case incidence to non-notification and considers that the figures are more accurate for years when typhus occurred in epidemic form.

The yearly average for 1929-1938 was slightly exceeded in 1941 and 1943 and more than doubled in 1944. War restrictions, especially the lack of soap, are held to explain the manifestations of typhus in exposed areas.

The intensity of infection was variable. In Othaø in 1944, two deaths occurred in 19 cases. Clinically, among the various degrees of intensity, it is stated that the most frequent form was "typhus *levissimus*".

The orthodox measures were taken and included isolation, delousing, organization of centres, use of 10 per cent DDT, inspection of incoming travellers and (from 1941) vaccination of sanitary staff with Cox-type vaccine imported from the United States.

RAYNAL, M J H Les rats et les puces du rat dans leurs rapports avec la pathologie humaine à Chang-Hai [Rats, Fleas and Human Pathology in Shanghai] Bull Soc Path Exot 1947, v 40, Nos 5/6, 212-38 [39 refs]

A title such as "Rats, Fleas and Human Pathology" conjures up immediately the subjects of plague and typhus. These are undoubtedly the major concern of a health authority in conducting and continuing large-scale examination or extermination of rats. In addition to these two important infections, an opportunity was afforded of investigating other possibilities of disease transmission from rat to man. Weil's disease, sodoku, salmonellosis, rabies, and melioidosis. Actually the article returns to an old contention of the author [this Bulletin, 1938, v 35, 781, 1939, v 36, 464, 983 and 1940, v 37, 256, 569], with newer verification, separating both murine epizootic and sporadic endemic typhus due to murine rickettsiae which are flea-borne, from the occasional outbreaks of epidemic typhus, spreading to man from rats, but which is afterwards louse-borne. Plague as a current problem may be dismissed from consideration (though not its potential dangers in times of unusual prevalence of *Xenopsylla cheopis*), because "it seems that its local implantation is not likely to be easy" and because no case of plague has been detected in Shanghai for twenty years.

As is natural, the preliminary study relates to the rats themselves. The brains of the rats were preserved at -15°C and, if the Weil-Felix serum test in any individual rat had given a high agglutination titre, the brain was triturated and inoculated intraperitoneally in two guinea-pigs. In some cases the material served as a test for the existence of rabies which, however, was never discovered. Other materials examined were bone marrow, urine and faeces, tested by culture for the frequency of *Proteus* and salmonellas. The rats were almost all (97 per cent) of the species *Rattus rattus* (*Epimys* black house rat) and there were almost no brown sewer rats (*R. norvegicus*). One reason for this may have been that the capture of the rats took place in a business or residential, and not in a port, area. Gravid female rats were found in greatest numbers at the end of winter and in spring. This should be the time to intensify a rat campaign. Males captured bear the proportion to females of 65.6 to 34.3. The fleas captured on rats were *Ctenopsyllus segnis*, *Xenopsylla cheopis*, *Ceratophyllus* *amsus* and *Ctenocephalides felis* in the relative proportions 62.8 : 26.3 : 10.8 : 0.1. Seasonally, *Xenopsylla cheopis* is prevalent in the warm weather of summer and autumn, and *Ceratophyllus amsus* from February to May. The former, admittedly the rat flea of plague, shows very variable prevalence, and abundance only at long intervals.

Typhus, and by this is meant classical exanthematic typhus in man, made its appearance in epidemic form in Shanghai in the years 1938, 1940 and 1942. This is a common experience in all wartime periods, and is due to crowding, misery and starvation, the disease manifested itself at an elevated endemic level.

from 1838 to 1945. A high correlation, positive or negative as the case might be with fluctuation from epidemic to endemic, was found between infected rats (diagnosed serologically) human cases of typhus and the number of rat carriers of fleas. In discussing the passage of infection from rat to man the author invokes the existence of very enzoo-epizootic murine localities and of soiled (rat-urine or rat-flea faeces) materials or virulent dust as the agents of transmission. The war conditions mentioned, when the vector becomes the louse and transmission is from man to man suffice to account for the epidemics of typhus experienced in Shanghai.

GIROUD P & JADIN J. Mise en évidence par absorption des anticorps du pouvoir antigène des tissus typhiques la éa. [Antigenic Potency of Washed Typhus-Infected Tissues shown by Agglutinin-Absorption.] C.R. Soc. Biol. 1947 June v 141 Nos. 11/12 579-81

By means of agglutinin-absorption reactions it was shown that crushed and washed tissues in which rickettsiae were cultivated retained a measurable quantity of antigen capable of fixing agglutinins [see this Bulletin 1945 v 42, 366]

H J O'D Burke-Gaffary

GIROUD, P & CIACCIO G. Pouvoir antigène de divers extraits de poulmon de lapin infecté des rickettsies. [The Antigenic Potency of various Extracts of Rabbit Lung Infected with Rickettsiae.] C.R. Soc. Biol. 1947 June, v 141 Nos. 11/12 585-6.

Potent antigens were easily obtained in solution from the lungs of rabbits infected by typhus rickettsiae. Of the methods tried the most successful were making suspensions of the lungs, in 10-20 per cent. methyl or ethyl alcohol, in 50 per cent. glycerin or in 8-10 per cent. sodium chloride.

The solutions when injected subcutaneously into rabbits caused a rapid rise in the rickettsia-agglutination titre of the animals serum. The solutions, except the one made with glycerin, retained their full potency up to 70 days. After desiccation they also remained stable, with or without preliminary precipitation by ammonium sulphate.

VAN DER SCHIEER, J BOHNEWEL, E. & COX, H. R. Diagnostic Antigens for Epidemic Typhus, Murine Typhus and Rocky Mountain Spotted Fever J Immunology 1947 Aug v 58 \ 4 365-75. [24 refs.]

The authors begin by giving a useful summary of the various methods of preparing antigens for the complement-fixation tests used in the differential diagnosis of epidemic typhus, murine typhus, and Rocky Mountain spotted fever.

It was found that epidemic and murine typhus vaccines prepared from infected yolk sacs by ether extraction and used as antigens gave non-specific reactions with Wassermann-positive syphilitic sera when the complement-fixation tests were carried out by the specially sensitive method of keeping the preparations at ice-box temperature for 18 hours. Little or no fixation occurred when the vaccines were purified by shaking with benzene and then concentrated by precipitation with sodium sulphate. Rocky Mountain spotted fever vaccines were treated in the same way. It then became possible to differentiate the last-named disease from epidemic and murine typhus, but in some cases epidemic typhus sera reacted nearly as strongly with murine antigen as with epidemic antigen.

In the three murine-typhus sera that were tested, the reaction against murine antigen was at a much higher titre than that against epidemic antigen.

With antigens prepared from purified and washed rickettsial suspensions by the method described by Plotz, strong cross-reactions were also observed with epidemic- and murine-typhus sera, but the titre was always higher with the homologous than with the heterologous rickettsial antigens

- ii REYNES, V & DELBOVE, P Evolution de la tuberculose expérimentale chez les cobayes surinfectés par un virus typho-exanthématique [**The Evolution of Tuberculosis in Guineapigs subsequently infected with Typhus Rickettsiae**] *Ibid* 211-12
- iii DELBOVE, P & REYNES, V Etude des réactions d'immunité chez des cobayes convalescents de maladie typho-exanthématique et surinfectés avec du Bacille de Koch [**Immunity Reactions in Guineapigs Convalescent from Typhus and subsequently infected with Tubercle Bacilli**] *Ibid* 244-5
- v REYNES, V & DELBOVE, P L'allergie tuberculeuse au cours des fièvres typho-exanthématiques chez le cobaye [**Tuberculous Allergy in the Course of Typhus in Guineapigs**] *Ibid* 245-6

i The authors show that in guineapigs infected experimentally with human tubercle bacilli, the course of murine or exanthematic typhus, subsequently induced, differs little from the course in non-tuberculous animals, but the murine strain, which previously had failed to produce the Mooser reaction, regained its capacity to do so, as a result of passage through tuberculous animals. A tropical rickettsial strain [presumably of tsutsugamushi disease] was much less virulent to tuberculosis than to normal guineapigs

ii In the second paper the authors show that tuberculous guineapigs later infected with the three strains of typhus rickettsiae lived much longer than tuberculous controls

iii In the third paper they claim that if animals which have recovered from infection with the three strains of rickettsiae are subsequently infected with tuberculosis, there is no loss of immunity (within 3-5 months of first typhus infection) when epidemic and tropical [? tsutsugamushi] strains are considered, but that there is loss of immunity in the case of a murine strain. In each case, homologous immunity only is referred to. [The numbers of guineapigs in each group (not more than 10) are so small that it is doubtful if the results are significant]

iv Tuberculous guineapigs which are infected with one of the three strains of rickettsiae after their tuberculin reactions have become positive, tend to become negative to tuberculin during the febrile period of the typhus infection, or during convalescence, but return to a positive reaction when recovery from typhus has taken place

DELBOVE, P & REYNES, V Recherches expérimentales sur l'évolution simultanée de l'infection tuberculeuse et des infections typhoexanthématiques chez le cobaye [**Experiments on the Simultaneous Infection of Guineapigs with Tubercle Bacilli and Typhus Rickettsiae**] *Ann Inst Pasteur* 1947, May, v 73, No 5, 439-50 [12 refs]

This is a rather fuller account of the work already reported by these authors in the four papers abstracted above. They were stimulated to conduct this study as a result of several clinical observations, but they do not state what these were

Charles Wilcocks

LEWICK, R. *Über Spätschaden nach Fleckfieber* [After Effects of Typhus Fever] *Med Klin* 1944 Aug 4 v 40 Nos. 31/32, 469-70.

Among 150 soldiers examined 4 to 12 months after attacks of typhus fever about two-thirds complained of one or more of the following symptoms — cardiac (96) irritability and restlessness (74) forgetfulness and inability to concentrate (64) headache (79) weakness (64) defects of hearing and ringing in the ears (52) and numbness of the limbs (82).

Electrocardiographic abnormalities were detected in only 14 cases, and among these there was seldom any evidence of myocardial damage. There were definite signs of damage to the nervous system in 91 cases including — exaggerated tendon reflexes (40) clonus and other spastic reflexes (34) diminished or absent abdominal reflexes (28) inequality of the pupils (45) loss of the pupal reaction to light (15) nystagmus (25) ptosis (15) facial-nerve lesions (27) hypoglossal-nerve lesions (24) Rombergism (16) diminution or loss of the knee jerk (17) tenderness on pressure over the nerves of the legs (21) sensory disturbances in the legs (18) and sensory disturbances in the arms (11).

In 32 cases, there was evidence of neuritis, mostly referred to the nerves of the legs. In 78 cases, there were indications of slight damage to the central nervous system.

In 78 cases, the cerebrospinal fluid was abnormal. In 60 of these there was an increase in the albumin and in 48 there was an increase in the cell count.

Presumably the patients had been selected for special investigation at a nerve clinic. If so the figures show only the relative frequency of the various signs and symptoms observed.

John W D Megees

WEI H & WEI, W P. Experimental Infection of Silkworm Pupae with Typhus Rickettsia. A Preliminary Report. *Chinese Med. J* 1947 May-June v 65 Nos. 5/6, 171-5 2 figs. & 1 chart.

Silkworm pupae were inoculated by the intracoeleomic route with murine rickettsial suspensions prepared from the lungs of infected mice. After the pupae had been kept at room temperature for six days, numerous rickettsiae were found in smears made from their throats. Suspensions of the intestinal and ovarian tubules of the pupae were inoculated into guinea-pigs, which developed febrile reactions similar to those caused by rickettsial inoculations.

Further study of the behaviour of rickettsiae in silkworms was impossible, because of the war situation that arose in 1944 when the experiments were in progress.

John W D Megees

WAR OFFICE. Scrub Typhus Investigations in South East Asia. A Report on Investigations by G.H.Q. [India] Field Typhus Research Team, and the Medical Research Council Field Typhus Team, based on the Scrub Typhus Research Laboratory South East Asia Command, Imphal [AUDY J R., et al.] Part I. General Account. 58 mimeographed pages of text & 11 Index pages (mimeographed) 1 map, 1 chart & 1 fig. Part II. Illustrations. Part III. Appendices (22 papers by individual workers) 1947 March. London War Office, AMD 7

This important Report deals largely though not entirely with wartime investigations carried out by a team of workers at the Scrub-Typhus Research Laboratory Imphal, near the Indo-Burma frontier.

The output of valuable work by the team was surprisingly large considering that the laboratory was fully staffed only from July to December 1945 though a few of the workers had been employed from April, 1945 and a rapidly dwindling number remained till March 1946.

Lt-Col J R Audy, R A M C, the officer in charge of the laboratory, has carried out the formidable task of editing and producing the three substantial volumes which make up the report, and readers will be surprised to find that the whole of this work was done between August 1946, and March 1947, especially as the editor himself has contributed more than half of the text and illustrations.

Lt-Col Audy craves indulgence for "many defects" in the report, but his readers will agree that these were inevitable in the circumstances and that they are trifling when weighed against the wealth of valuable material that has been made available to students of the fevers of the typhus group. Considered as a set of collected papers, the only drawbacks to the report are the relegation of the illustrations to a separate volume and the long list of corrigenda and addenda. But the report is much more than a collection of articles, as will be gathered from the following review of its contents.

Part I: General Report Account

The opening paper, of 19 pages, is on "The Occurrence and Identification of the Typhus Group of Fevers in the South East Asia Command". The authors are Col M H P SAYERS, R A M C, Deputy Director of Pathology, S E A C, and Brigadier I G W HILL, R A M C Consulting Physician, S E A C. The paper, written in 1945, deals chiefly with the incidence, geographical distribution, epidemiological features, and laboratory studies of scrub typhus in the Eastern Theatre during the years 1941-44. An apology is made for the use of the name scrub typhus whose only justification is its almost universal adoption, the classical name is tsutsugamushi fever.

The first outbreak recorded during the war was one of 107 cases seen in 1941 by G SINGH in a rural area of Central Burma [see this *Bulletin*, 1945, v 42, 883]. This outbreak, though definitely of the "OXK type", was suspected by Singh to be louse-borne, presumably because mite-borne typhus was not expected to occur as an epidemic.

Little is known of the occurrence of the disease in the area during 1942. Most of the outbreaks referred to by the authors as occurring in 1943 have afterwards been described in papers by their observers. They include (1) 121 cases in a battalion of a British regiment not far from Imphal, reported by TATTERSALL and PARRY [this *Bulletin*, 1946, v 43, 430] (2) 500 cases on the India-Burma border in 1943 and early 1944 reported by TATTERSALL [*ibid*, 28] and (3) 114 cases of typhus fever of which 96 were of the OXK type in an Indian Military Hospital in Calcutta, reported by Lusk [*ibid*, 246].

The only outbreak of a typhus fever other than scrub typhus mentioned by the authors is one that occurred at Ranchi in Bihar, India, early in 1943. In this, 33 persons became infected in waste-land in January 1943, nearly all the patients gave a Weil-Felix response of the "indeterminate type", none gave an OXK reaction, and from the bibliography appended to the paper it appears that B T BOWES described the outbreak as one of "Tick-Borne Typhus".

During 1944 about 5,000 cases with 350 deaths are said to have occurred in Burma and Eastern India.

(2) In a brief paper of seven pages, entitled "The Medical Research Council Scrub-Typhus Commission", Dr R LEWTHWAITE, Director of the Institute for Medical Research, Kuala Lumpur, describes the origin and work of the Scrub Typhus Commission established by the Medical Research Council in 1944, the original members were, himself as Field Director, with Dr Kenneth MELLANBY and Charles D RADFORD as Entomologists. Dr H C BROWNING was appointed in 1945 as Experimental Biologist, but his work was interrupted by an attack of malaria followed by one of scrub typhus contracted in a

hyperendemic area in Burma. Mr H T M Gordon was appointed as associate to Dr Browning.

(3) Andy in an article of 26 pages contributes "A Review of Investigations on the Epidemiology of Scrub Typhus in South-East Asia 1945-1946." This paper which summarizes the work done by members of the staff of the Imphal Laboratory and other workers, will be found very useful by students of the typhus fevers who have not time to read the whole report. A bibliography of recent contributions on the subject of scrub typhus is appended.

(4) Andy in an article of four pages also describes "The Establishment of the Research Laboratory at Imphal (Manipur)."

(5) A Subject Index (11 pages) to the three volumes of the Report completes Part I.

Part II

This consists of 135 illustrations reproduced on 69 sheets of foolscap-size art paper.

Part III Appendices

This consists of 22 papers, of which 20 are by Lt.-Col. Andy and other members of the Imphal research team, and two are by Dr M. T. PARKER, late Major R.A.M.C. from the District Laboratory Calcutta.

Most of the papers deal with investigations carried out during the short period of existence of the Imphal Laboratory. The papers can be very roughly classified according to the chief subject matter as Epidemiological, Entomological, Bacteriological, and Survey but most of them deal with more than one aspect of the disease.

The volume contains more than 200 foolscap-sized pages in small (petit roman) type, and much of the subject matter is of a technical nature so that it is obviously impossible to do justice to each paper. Some of the articles though published with the consent of the authors, have been collated by the editor from reports and have not been revised by the workers concerned. Several of the papers are expected to be published in complete form at a later date.

Papers dealing chiefly with Epidemiology

In Appendix I (14 pages and 7 illustrations) Andy contributes "A Survey of Scrub Typhus in Burma, 1945." He shows that though previous records of the occurrences of the disease in Burma were scanty infection was found to be widespread throughout the country and to include such unexpected localities as waste land in urban areas like those of Rangoon and Mandalay.

In the 12th Army 598 cases occurred between March and December 1945. The proved vector was *Trombicula deliensis* and the chief animal reservoirs were *Bandicota bengalensis* and *Rattus rattus* though tree shrews and squirrels were of local importance.

Strains of *Rickettsia tsutsugamushi* (now more commonly known as *R. orientalis* see this Bulletin 1943 v 40, 828) were recovered from one bandicoot and one rat, in addition to the strains isolated by Kalra from various sources including patients, and a strain earlier recovered from *T. deliensis* larvae on the Indo-Burma border.

Methods of preventing the disease in peace-time are discussed. Thorough ground clearing followed by cultivation of grazing, and rat control, are likely to be effective, but rat control must be carried out a month or two after the onset of the rains. Earlier operations may increase the risk of transmission by mites and later measures will not reduce the second generation of larvae. Personal protection by dimethyl and dibutyl phthalate and by benzyl benzoate is discussed in general terms.

In Appendix 2 (46 pages and 68 illustrations) Audy presents "An Ecological Study of Scrub Typhus". The ecological features of the disease in areas in Assam, Manipur State, Burma, Ceylon, The Maldives Islands, and India, are described in detail. Statistics of the case-incidence and descriptions of the terrain are supplied for each of a large number of infected localities in which surveys were made.

A section of the paper contains a summary of the factors concerned in the distribution of mites in relation to the ecology of the disease, and another deals with the ecology of the disease in relation to the ecology of the mites and mammals concerned in transmission. In the latter section the reader is confronted with a number of technical terms which the author mercifully defines, otherwise the uninitiated would be puzzled by such names as climatic climax, seral community, subclimax, and scrub constellation.

In Appendix 9 (5 pages) M T PARKER writes on "Scrub Typhus among Troops in the Calcutta Area in 1942 and 1943". In 1943 there were 195 cases of typhus-group fevers classified as follows: scrub typhus, 150, "X19 typhus", 23, "indeterminate" (OX2 type) 4, and "clinical typhus", 18. Most of the cases of clinical typhus were believed to be scrub typhus with a negative Weil-Felix response, and most of the "X19" cases were thought to be murine typhus. [Some of the cases of these two types and the four cases of the OX2 type may have been tick-borne.] Lusk has already discussed the features of the 114 cases of typhus seen in the Indian Military Hospital, Calcutta in 1943 (see this *Bulletin*, 1946 v 43, 426). No eschar was seen in any of the cases. In Appendix 13 (5 pages and 1 illustration) Major S Lal KALRA, I A M C, Bacteriologist of the General Headquarters India, Research Team, and Squadron Leader C D RADFORD R A F, describe "Scrub Typhus in Ceylon". Little was known of the existence of the disease in Ceylon till the occurrence of a dramatic outbreak in which 756 persons (713 Africans and 43 British) belonging to a body of troops engaged in manoeuvres in scrub land from 11th to 15th December, 1943 were attacked within a period of seven days from the 22nd December onwards. The mortality rate was 1.3 per cent among the Africans and nil among the British. An eschar occurred in 58 per cent of the cases.

In a short summary of a paper by Radford on "Scrub Typhus Research in Ceylon" there is a statement of the infestation of bandicoots, rats, shrews, etc., by *T. deliensis* and *Ascoschöngastia indica* Hirst, 1915.

In Appendix 14 (6 pages and 3 illustrations) Kalra deals with "Scrub Typhus Investigations on Addu Atoll, Maldives Islands", and refers to the findings of Radford who collaborated with him in the work.

The most interesting feature of the disease in the small island surveyed was that without the use of mite repellents or vaccines complete control of infection was established by clearing and keeping clear the island of all low vegetation. After the initiation of this procedure there was at first a rise in the number of cases, but this was followed by a rapid fall from 33.4 per mille in 1942 to 2.4 in 1944. During the time of the survey—November 1944 to February 1945—there were no cases, and although rats and shrews infested with *T. deliensis* were found, no rickettsiae could be isolated from the tissues of 111 rats and 32 shrews which were examined. The case-fatality rate was 2.4 per cent in 600 cases that occurred among Indian troops on the Island.

In Appendix 15 (2 pages) Kalra deals with the 'Distribution of Typhus Fevers in India'. He has already reported his findings [see this *Bulletin*, 1947, v 44, 575] but he now rightly states that the "OX19" cases presumably include "some tick typhus" in addition to murine typhus but he still bases his classification of the cases into scrub murine, and tick typhus, on the Weil-Felix response, which admittedly cannot be relied on to differentiate murine

typhus from tick typhus. [Complement fixation tests will doubtless throw light on the distribution of the typhus fevers in India.]

In Appendix 18 (7 pages and 4 illustrations) Kalra makes a "Preliminary Report of Typhus Investigations in the Kumaon Hills, United Provinces, India" during the months August to October 1946. In the country round the three small lakes of the Bhim-Tal area, 9 strains of rickettsiae were isolated from 15 rats, and 5 strains were recovered from 17 batches of mites, chiefly *T. deliensis*. Many animals, domestic and wild including rats, were infested with *Rhipicephalus sanguineus* and four other species of ticks were found.

More than 2,000 ticks were collected in the region by the flag method different batches of these were inoculated into 23 guinea-pigs, of which 9 reacted 4 doubtfully and 5 definitely including 3 in which there were redness and swelling of the scrotum.

Trombiculid mites and various ticks were found on rats in five other localities, including Almora, where an average of 8 ticks was found on all the 6 rats captured and 2 of the 3 guinea-pigs inoculated with separate batches of the ticks reacted with fever and scrotal swelling.

Altogether 20 strains of *Rickettsia tadsugensis*: 7 tick-strains related to *Dermacentorossus* [*Rickettsia*] *rickettsii* and one suspected murine strain, were isolated in the area of the survey.

In a later Appendix (17 dated February 1947) Kalra gives further details of the investigation of ticks in the Kumaon Hills. Among total of 20 batches of ticks from various localities 9 from Bhim Tal, consisting of *R. sanguineus* and *Boophilus* sp., and 3 from Almora, consisting of *Ixodes ricinus* caused fever and scrotal reaction in guinea-pigs and rickettsia-like bodies were found in spleen smears. Complement-fixation tests were carried out with Rocky-Mountain-spotted fever antigen on the sera of 9 of the guinea-pigs 2 of these reacted at a titre of 1-10 both were from animals inoculated with *R. sanguineus* from Bhim Tal, the others gave negative reactions.

In this appendix Kalra also reports the isolation of a similar tick strain of rickettsia from a batch of 11 ticks (*Haem. physalis leachi* var *indica*) found on a rat in the Imphal area in November 1945 this rat was also infested with *T. deliensis* mites but these were not infected though the host rat was found infected with *R. tadsugensis*.

[These remarkable findings will doubtless stimulate renewed interest in tick typhus in India. The strains of rickettsiae isolated in the neighbourhood of Bhim Tal and Almora will probably be closely studied.]

In Appendix 23 (13 pages and 6 illustrations) H. C. Brownrigg and Kalra present a Report on a Scrub Typhus Outbreak in the Mandalay Area, May to July 1945.

The number of cases in this outbreak was 103 among 54 cases tested the agglutination responses were aberrant in 6 of these 3 were of the OX19 type, 2 were OX19 combined with OXK and 1 was OX19 with OX2.

A detailed survey was made of the epidemiological conditions. Laboratory mice in cages were exposed in areas in which infection had occurred among 50 mice 3 became infected with scrub typhus.

An investigation of the fauna of the soil of several localities was carried out by methods described in the paper. Trombiculids were, surprisingly absent even from the soil of places where experimental mice had become infested or infected, so that the habitat of the nymph and adult forms of the mites remained a mystery.

Papers dealing with Entomology

In Appendix 3 (18 pages and 12 illustrations) Andy discusses The Biology of Trombiculid Mites in Relation to Transmission of Disease.

The most important observation recorded in this paper is that *T. deliensis* remains attached to its hosts for two to four days, as is the case also with *T. akamushi* of which it may be a variant. This feeding time is shorter than that of species of *Ascoschöngastia* which remain attached for about a week, and much shorter than that of *Walchia* and *Schöngastiella* which have a feeding time of about four weeks. Taking into account the infestation rates of rats in the Imphal area, it is estimated that 3,000-4,000 larvae of *T. deliensis* feed on each rat in a year, so that this mite has a great advantage over other potential vectors which have annual "turnovers" ranging from 800 to only 50 mites.

A summary of this highly instructive paper will be found in the author's Review in Part I.

In Appendix 5 (8 pages and 2 illustrations) Audy and Major H. M. THOMAS, R. A. M. C., Experimental Biologist, contribute a useful "Note on Techniques and Field Collections."

Appendix 7 (6 pages) is by Sergeant T. J. LAWRENCE, R. A. M. C., Entomologist, who writes on "Species of Trombiculid Mites in Manipur and Burma." Many new species described by the author and Radford are included, and opinions on several of these are added by Dr. Henry S. FULLER, formerly attached to the U. S. A. Typhus Commission at Myitkyina.

In Appendix 10 (3 pages) and Appendix 11 (6 pages and 6 illustrations) THOMAS deals with "Observations on the Behaviour of *T. deliensis* in Soil", and "Observations on the Development of the Nymphophane [pupa] of *T. deliensis*."

These papers will be of special interest to professional entomologists.

In Appendix 19 (5 pages and 7 illustrations) Kalra contributes "Reports on Histological Investigations" in which he describes histological techniques suitable for the investigation of mites in a field laboratory, by making serial sections. The paper includes observations on the internal structure of *T. deliensis*, on the histopathology of the eschar, and on the lesions produced in the skin of the rat by infesting mites.

Appendix 21 is by K. COCKINGS, Entomologist, who, in a short paper of 4 pages with 2 illustrations, deals with "Breeding and Trapping of Trombiculid Mites," and gives details of the technical methods employed.

Papers on Bacteriology and Serology

Appendix 8 (2 pages) is by M. T. PARKER who describes his work on "The Transmission of the infective Agent to Experimental Animals."

In December 1943, the author, working at Calcutta, isolated *R. tsutsugamushi* by inoculating the blood of a patient into the anterior chamber of a rabbit's eye. By the same method, he isolated the organism from the peritoneal exudate of three guinea-pigs which had been inoculated at Imphal (by Lt. Col. Sayers, R. A. M. C.) with pooled blood clot from several patients. Two other strains were isolated later, one from near Imphal, the other from North Burma, both from guinea-pigs inoculated intraperitoneally with blood from patients.

Guinea-pigs inoculated in this way were found very suitable for the transport of strains to distant laboratories.

In Appendix 12 (13 pages and 13 illustrations) Kalra, assisted by Sergeant J. D. BOWER, R. A. M. C., presents a "Report on Field Investigation on Scrub Typhus in Manipur, Assam."

The recovery of 19 strains of *R. tsutsugamushi* from the following sources is described—(a) From patients, 5 strains were isolated by inoculation of blood or blood clot into guinea-pigs or white mice. The patients were infected in the Imphal or N. W. Burma areas. One of the strains was recovered from the blood of Dr. H. C. Browning on the 4th day of his illness, and a sample of his blood

taken on the 18th day was examined in the U.S.A. by "Dr Sheppard [presumably C. C. Shepard], who reported a positive reaction with the complement-fixation test at a titre of 1-32 against Gilliam (Assam) antigen and at a titre of 1-512 against Karp" (New Guinea) antigen. [Striking variations in the responses of the same sera to different antigens have been reported by Buxton (see this Bulletin 1947 v 44 61.)]

(b) From rats (six strains) from a field-mouse and a tree-shrew (one strain each)

(c) From larval mites, six strains were isolated all the batches of mites employed were collected from rats in the area south of Imphal two of the strains were from batches of mites consisting solely of *T. deliensis* the other positive batches were of mixed species, but all contained a certain number of *T. deliensis*.

Strains were also isolated from five of the laboratory white mice that had been exposed to mite attack by being placed in cages on the ground at Mandalay Fort.

Details are given of the extensive work done on the strains nine of them were maintained for 8 to 20 passages through white mice, in which their virulence usually rose during the earlier passages. Transfers of 14 strains were made from mice to guinea-pigs, in which various reactions occurred, but only one strain, originating from a tree-shrew caused peritoneal exudate containing abundant rickettsiae.

A description is given of the varied responses to inoculation of strains into seven rhesus monkeys obtained from Calcutta and regarded as free from previous infection. Some of the monkeys showed cross-immunity when challenged by a second inoculation with a different strain, but others showed no immunity or only partial immunity.

One monkey inoculated with a mite strain developed OXK agglutinins up to a titre of 1-320 (on the 34th day) this monkey was again inoculated on the 39th day with the tree-shrew strain already mentioned the response was rise in the OXK agglutinins, whose titre became 1-1,280 on the 60th day after rem inoculation, and a disappearance of the OXK agglutinins. This tree-shrew strain did not protect any of four mice from death when they were challenged later by a mite strain. [No mention is made of the possibility that the tree-shrew strain might have been of the tick borne type the author states elsewhere that it resembled *R. tsutsugamushi* in its morphology and behaviour in animals.]

Local rats, though regarded as free from the risk of previous infection, were not satisfactory as test animals.

The isolation of a strain from ticks in the area has already been mentioned.

Appendix 17 (8 pages) by Kaira contains Miscellaneous Supplementary Notes, dated January-February 1947 in which the isolation of tick strains already mentioned is described. Among other recent studies are the following:—

(1) Three rats were inoculated with strains of *R. tsutsugamushi* two from Imphal and one from North Burma six months later the rats were found free from infection and were inoculated with Bham-Tal strains of the same organism all three became infected but further experiments are contemplated to find whether infection confers lasting immunity against homologous strains.

(2) Cross-immunity tests were carried out in which rabbits were inoculated intraocularly with strains of *R. tsutsugamushi* three of which were from the Kumaon Hills, two from Ceylon, and one each from Burma and Imphal. After recovery the inoculation was repeated with strains from Kumaon five of the rabbits were found immune, but one of the Ceylon strains and the Imphal strain had conferred no immunity. Immunological differences among various strains are therefore suggested.

(3) A list of ticks collected in Imphal and the Kumaon Hills is given, these were identified by Dr M SHARIF of the Haffkine Institute, Bombay

In Imphal the commonest species was *Haemaphysalis leachi indica*, found on rats and tree shrews, the only other tick found on rats was *R sanguineus*. In the Kumaon hills *R sanguineus* was the most abundant, it was found on rats, dogs, sheep, cows, and horses, the only other tick found on rats was *Ixodes ricinus*, in Almora

(4) A note by Audy is included in this Appendix, it is on "An outbreak in Central India, Apparently of Tick Typhus with Eschar". Six persons were attacked in February 1945, in Bhopal State, Central India. Five of the patients had obviously been infected on the same day in a "pin-point area", and all of them had an attack which clinically and serologically conformed to the picture of tick-borne typhus with eschar. The sixth patient was infected a short distance away, he had a similar attack, but without eschar. Audy suggests that the cases with eschar may have been of the boutonneuse-fever type. He states that so far as he knows cases of tick typhus with eschar have not been reported from India. [The reviewer, about 15 years ago, saw a typical case of tick typhus in which there was a pronounced eschar at the site from which the patient had removed a tick just before the onset of the fever, this case was not recorded, the patient was seen in a hospital at New Delhi, by the courtesy of Lt Col Aspinall I M S. The presence or absence of an eschar in tick-borne typhus may be fortuitous, just as it is in scrub typhus.]

In Appendix 18 (4 pages) Kalra discusses "The Value of Proteus Agglutinins as an Endemic Index of Scrub Typhus, and in Differentiating Sub-Groups of Tropical Typhus". Sera of many animals captured at Imphal and Addu Atoll were tested for the presence of OXK agglutinins. A considerable number reacted at titres of 1-20 to 1-80, one flying fox and two lizards reacted at 1-160. Among 30 rats examined, 4 reacted at 1-80, but 4 reacted with OX19 and 2 with OX2 at the same titre. No rise in the OXK titre occurred among rats inoculated with scrub typhus at Imphal. In a small proportion of scrub-typhus patients at Imphal, Mandalay, etc, atypical reactions occurred and were verified by repeated tests, in most of these the reaction was of the OX19 type, in a few it was of the combined OX2 and OX19 type. The author states that "the clinical disease in all these cases was identical". From these and other findings recorded in the paper, and from a study of the literature, the author concludes that though the Weil-Felix test is a useful aid to diagnosis it "cannot always be relied on to differentiate sub-groups of the disease". [Complement-fixation tests might throw light on the significance of these anomalous reactions.]

Papers on Survey Methods

Appendix 4 (6 pages) is a preliminary report by Audy on "Applications of Air Photography to Research and Survey".

The author claims that air photography is a very useful preliminary to a survey the object of which is to avoid endemic foci of scrub typhus, and that it is also of value in the collection of information for ecological and other investigations. The numerous photographs illustrating Appendix 2 show clearly the kind of information that can rapidly be obtained by air photography.

Appendix 6 (7 pages), also by Audy, deals with "Field Surveys and Methods of Control". Concise instructions are given with regard to the methods and equipment employed in surveying known or suspected scrub-typhus areas. There is also a useful summary of the methods of controlling the disease.

In Appendix 22 (4 pages) BROWNING and GORDON describe "Methods of Field Anaesthesia in Laboratory Mice and Wild Rats". Details are given of the duration of anaesthesia resulting from the administration of several drugs in various doses. Bromethol given intraperitoneally in doses of 0.012 cc

to rats caused anaesthesia lasting about one hour—half this dose rendered mice unconscious for about three hours. The drug had the special advantage of quick action, so that when given to animals lightly anaesthetized by chloroform or ether consciousness was not regained during the brief period needed for the production of its effect. There was also a good margin of safety.

Acknowledgments

Among other acknowledgments, Lt.-Col. Audy and Dr. Lewthwaite express their gratitude for helpful and friendly co-operation by Col. T. T. MACKIE and the other 13 members of the U.S.A. Typhus Commission in North Burma whose studies of the disease from December 1944 to November 1945 have already been the subject of a preliminary report [see this *Bulletin* 1946 v 43, 917 and 1132].

Dr. Lewthwaite also refers to the important work of the Australian entomologists, McCULLOCH and WOMERSLEY [*ibid.* 1945 v 42, 28, 324 and 369]. Valuable contact was made with these workers and also with members of the U.S.A. Typhus-Commission team in New Guinea [*ibid.*, 991 and 993].

KALRA, S. L. Inclusion Bodies in *Rickettsia orientalis* Infection. *Indian Med. Gaz.* 1947 June v 82, No. 6, 326-7

In the course of his isolation of 25 strains of *Rickettsia orientalis* from various sources in 1945 the author observed homogeneous intracellular inclusion bodies similar to those described by GIROUD and PANTHIER [this *Bulletin*, 1947 v 39, 753] as being associated with classical rickettsiae during their adaptation to growth in the lungs of rabbits. The author detected the bodies in epithelial cells in Giemsa-stained smears of peritoneal exudate of mice inoculated by the intraperitoneal route. The bodies were seen in only a few of the strains investigated.

John W. D. Meyer

DAVIS, G. E., AUSTRIAN, R. C. & BELL, E. J. Observations on Tsutsugamushi Disease (Scrub Typhus) in Assam and Burma. The Recovery of Strains of *Rickettsia orientalis*. *Amer. J. Hyg.* 1947 Sept., 46, No. 2, 298-98.

The recovery of 85 strains of *Rickettsia orientalis* in Assam and Burma has already been described in a preliminary report by MACKIE and other members of the China Burma-India section of the U.S.A. Typhus Commission [see this *Bulletin* 1946 v 43, 917 and 1132].

The authors now give fuller details of their special investigations, including a description of the technical methods employed.

They state that Japanese workers had previously produced evidence of the occurrence of transovarial transmission of *R. orientalis* but that their own experiments were the first to demonstrate the actual presence of rickettsiae in the tissues of a host (white rat) experimentally infested with laboratory-reared offspring of infected mites (*Trombicula deliensis*). They also claim to have been the first to recover *R. orientalis* from larval trombiculid mites collected from the Yunnan buff-breasted rat (*Rattus floricatus yunnanensis*) from the large shrew (*Suncus murinus sub-cinereus*) from the Assam tree shrew (*Tupaia belangeri versicolor*) and from the tissues of the above-named rat and tree-shrew.

The gerbilles—*Gerbillus gerbillus* and *G. pyramidum*—were found superior to white mice for the microscopic demonstration of rickettsiae, especially in primary isolations of the organisms.

REDDY, D J **Scrub Typhus in North Burma** *Indian Med Gaz* 1947, June, v 82, No 6, 330-33

The author has made an analysis of the chief features observed in 68 patients who formed part of "nearly 100 cases" of scrub typhus treated in an Indian General Hospital at Meiktila from May to November 1946

The nationalities of the patients were Indian 38, Burmese 19, Japanese 6, and British 5 The fatality rate was 4.5 per cent, an eschar was seen in 37 per cent, adenopathy in 80 per cent, and a rash in less than 6 per cent

Apparently the diagnosis was made only in cases in which the *Proteus* OXK titre rose to 1-320 or over at some stage, in 69 per cent of the cases this titre was reached by the end of the second week One of the patients had been inoculated against the disease, his attack was mild and his OXK titre never rose above 1-320

An unstated number of inoculated persons were tested weekly after inoculation, their OXK titres were found to have "a maximum of 1-40"

During the first week, the majority of the patients showed Widal titres of 1-160 to 1-320, but during the second and third weeks these titres declined

GREENBERG, M & PELLITTERI, O **Rickettsialpox.** *Bull New York Acad Med* 1947, June, v 23, No 6, 338-51, 5 figs & 2 charts

This is a clear and succinct description of rickettsialpox, the interesting rickettsial disease whose very existence was not known until the middle of 1946 [see this *Bulletin*, 1947, v 44, 411, 897]

The authors give an account of the thorough manner in which the disease was investigated within a period of a few months by a team of experts, of which they were members

The only important feature of the disease that remains unknown is its geographical distribution outside the limits of New York City

John W D Megaw

SHEPARD, C C. **An Outbreak of Q Fever in a Chicago Packing House** *Amer J Hyg* 1947, Sept, v 46, No 2, 185-92, 2 figs [10 refs]

By complement-fixation tests a retrospective diagnosis of Q fever was made in connexion with a sharp outbreak of 33 cases of fever among 81 men engaged in slaughtering sheep and calves in a packing house in Chicago, during August, 1946

The outbreak was similar in most respects to the one that occurred in Amalhiro, Texas, in March 1946 [see this *Bulletin*, 1946, v 43, 924] There were no deaths The original clinical diagnosis in most cases was pneumonia or influenza

The patients had been engaged in handling and cutting up freshly killed animals and the highest attack rate was among those most exposed to splashing with blood and exudate from the carcasses

Droplet infection was regarded as the most likely mode of transmission of infection There was no evidence of bites by ticks or other arthropods, and no cases occurred among workers who handled the animals before slaughter

John W D Megaw

EKLUND C M, PARKER, R R & LACKMAN, D B **A Case of Q Fever probably contracted by Exposure to Ticks in Nature** *Pub Health Rep Wash* 1947, Sept 26, v 62, No 39, 1413-16

At the end of March 1947, a young man found himself infested by numerous ticks (*Dermacentor andersoni*) in the Bitterroot Mountains, Montana, he

crushed a number of the ticks with his fingers. Seventeen days later he became ill and suffered from headache and malaise for about 7 days.

Complement fixation and rickettsia-agglutination tests for Q fever were negative on the 8th day but on the 24th and 36th days both tests were positive. The titres observed with the former test were 1-128 to 1-512 against four different antigens, an Australian, two Italian, and the original American strain. The titre of complete agglutination of the Australian strain of rickettsiae was 1-40.

The authors state that the question arises whether infection could have been acquired through an abrasion of the skin, or even through the unbroken skin as is the case in Rocky Mountain spotted fever.

YELLOW FEVER

HOCKING, K. S. The Use of Bamboo Pots to Indicate *Aedes* Prevalence. *Bull. Entom. Res.* 1947 Aug v 38, Pt. 2, 327-33.

Various techniques have been used in attempts to estimate mosquito populations. With *Aedes* the commonest have consisted of counts of larvae or adults in houses, but these cannot be used in rural areas, e.g. around an aerodrome with no houses. The "Bamboo pot" technique gets over this difficulty. The "pots" consist of lengths of bamboo about 3 in. in internal diameter and one foot in length, filled with water and exposed in varying numbers and different localities, for periods of five days. Up to 75 per cent. were found to contain larvae in the experiments carried out. It is shown that this method of estimating *Aedes* prevalence has fewer inaccuracies than those used previously and it is particularly sensitive and valuable in well-controlled areas with few other breeding places. It can also be used in rural areas.

Kenneth McIlanby

WADDELL, Mary B. & TAYLOR, R. N. Studies on the Cyclic Passage of Yellow Fever Virus in South American Mammals and Mosquitoes. III. Further Observations on *Haemagogus equinus* as a Vector of the Virus. *Amer J Trop Med.* 1947 July v 27 No. 4 471-6.

The authors first discuss the various factors which affect the chances of mosquitoes becoming infected with the yellow fever virus and their ability to transfer the infection to a susceptible vertebrate host. These factors have all been considered and investigated recently in previous papers by the authors and others working in South America [see especially this *Bulletin* throughout 1948]. They consider it virtually impossible to duplicate the conditions in any two transmission experiments and unless the conditions are the same results may vary irrespective of the vector employed.

In order to circumvent this contingency in the experiments here reported, a vector chosen as a standard for comparison was introduced and submitted to the same conditions as the vector under study. The efficiency of the latter was then determined by comparing its transmission ratio with that of the standard vector.

First the alternate cyclic passage of yellow fever virus through *Haemagogus equinus* and *Callitrix aurita* as described in a previous paper [see this *Bulletin* 1946, v 43 33 1947 v 44 309] was repeated for seven cycles. In this experiment, six to eighteen mosquitoes were allowed to feed each time.

A second experiment was carried out in which each individual mosquito was tested for virus. Infected marmosets were exposed at the same time to

normal *H. equinus* and *Aedes aegypti*. Blood was removed from the marmosets immediately before the mosquitoes fed and was tested for virus content. The mosquitoes which imbibed blood were segregated and stored in an atmosphere having a temperature of 28-30°C and humidity of 70 to 90 per cent. On 14th, 18th and 21st days thereafter they were permitted to feed individually on baby mice 2 to 3 days old. For each surviving *H. equinus* an *Aedes aegypti* that had taken the infectious meal at the same time was tested. Though the number of mosquitoes tested was small, owing to high mortality of *H. equinus*, the ratio of transmission was higher with *Aedes aegypti* irrespective of the length of incubation of the mosquitoes.

When the titre of circulating virus in the source marmoset was low at the time of feeding, few mosquitoes transmitted the infection. By this method of comparison against *Aedes aegypti*, a ratio of transmission may be obtained which should serve for comparing one sylvan species with another.

F O MacCallum

DENGUE AND ALLIED FEVERS

FLEMING, R F & FRENCH, J M. Dengue in Iraq. *Trans Roy Soc Trop Med & Hyg* 1947, July, v 40, No 6, 851-60.

An account of an outbreak of febrile disease in a military hospital in Iraq in late 1944 among British, Indian and Arab troops. Of a total of over 60 cases, careful clinical and pathological investigations were carried out in 24 selected on account of lymphadenitis. The results of all pathological examinations, except for the presence of an almost constant leucopenia, were negative.

In the cases selected for special examination leucocyte counts varied from 8,200 to 4,000 per cmm, no absolute lymphocytosis suggestive of glandular fever was found, and Paul-Bunnell tests were negative. *Aedes aegypti* were present in the neighbourhood. The patients usually had a sudden onset with chilliness but no rigors, the temperature rising to 104°F, severe headache, joint pains, backache and generalized aching were experienced. Severe occipital headache with pain and rigidity at the back of the neck in some cases suggested meningitis, but this was not confirmed.

The primary rash was macular or maculo-papular, appearing from the second day onwards, sometimes being so profuse as to suggest typhus, while a secondary rash, when this was present, appeared on the last day of fever and was sometimes hard to detect. The majority showed neither primary nor secondary eruption. Bronchial symptoms with widespread rhonchi were often found, the glands most commonly enlarged were the posterior cervical and epitrochlear groups. Bradycardia was almost always present.

Typical "saddle-back" temperatures were found in only three cases. The temperatures fell to normal on the 6th or 7th day, sometimes rising again to 99°-99.6°F for a few days. Albuminuria was absent.

Laboratory examinations included numerous blood smears, total and differential leucocyte counts, blood cultures, agglutinations against the enteric and *Brucella* groups, Weil-Felix reactions, Wassermann and Kahn tests, examination for leptospirae. Diagnosis was made on the clinical course of the disease, the leucopenia, and the negative laboratory tests.

[The above, though not all typical "text-book" cases, certainly appear to have been dengue or some closely allied illness. There is a group of 6- or 7-day fevers, the manifestations of which seem to vary a good deal in different

outbreaks and localities. The reviewer while in Iraq in 1920 and 1921 saw many cases of three-day (sandfly) fever but none clinically diagnosable as dengue.]

PLAGUE

SWELLENGREBEL, N. H. Interhuman Transmission of Bubonic Plague. *Bull. Office Internat. d'Hyg. Publique*. 1946 Oct.-Nov.-Dec. v 38, Nos. 10-11-12, 788-91 [French version 784-7]

Interhuman transmission of bubonic plague reduces to a consideration of the efficiency in this respect of the human flea *Pulex irritans*. That it can become infected seems unquestionable as also that it can remain infected for at least 21 days. Moreover in North Africa, where this contention that plague may be transmitted by human fleas arouses infestation by these fleas is of such degree as is unknown in those parts of the world where flea transmission has been very thoroughly studied, India and Java. After consideration of all the arguments, Swellengrebel comes to the conclusion that rat fleas can be carried along in cargoes and by human beings without being accompanied by rats and that antiplague measures must include disinsectionization as well as deratization, together with control of human traffic. His final pronouncement is —

Whatever the part *P. irritans* takes in plague transmission may ultimately prove to be antiumurine measures to prevent plague are highly specialised and directed against the murine population occupying human habitations only not, necessarily against other species, of rats, however important they may be from other points of view

MANI Chemotherapy in Plague. *Bull. Office Internat. d'Hyg. Publique*. 1946 Oct.-Nov.-Dec. v 38 Nos. 10-11-12, 800-807 [French version 792-9]

Part I of this communication deals with chemotherapy and consists of abstracts of reports from 1940 onwards comparing the results obtained with sulphathiazole and sulphadiazine. The control used in comparison was iodine intravenously. Part II gives the use of a broth plague vaccine originally substituted for agar because of war difficulties. The broth vaccine, acid hydrolysate of casein of Muller and Johnson, has proved by mouse protection test to be as potent as the agar vaccine is no more toxic and has the advantage of better keeping qualities.

CHOLERA

REIMANN, H. A. Further Note on the Classification of Vibrios of the 1945 Cholera Epidemic in Chungking. *Amer. J. Trop. Med.* 1947 July v 27 No 4 503.

Vibrios from several patients in the epidemic of cholera in Chungking in 1945 were classified as being of the Ogawa type in one laboratory [this *Bulletin* 1947 v 44 423]. Dr BURROWS of the University of Chicago examined the strains and reported different results. He has recently proposed a new classification of the cholera vibrio on a serological basis (*ibid* 422).

It would appear that, in cholera epidemics, either single type strain or different serological types of the cholera vibrio are rampant. Questions arise

as to whether (a) epidemics begin from distribution of a single type and others appear as a result of bacterial dissociation or type transformation or if epidemics are caused by one or more stable types of vibrio, and (b) if vibrios without antigen A—and presumably not cholera vibrios—may cause clinical cholera, or if they are dissociant culture phase forms of pathogenic vibrios brought about by extra corporeal growth

H J O D Burke Gaffney

YEN, C H A Differential Medium for the Isolation of *V. cholerae* Chinese
Med J Shanghai 1947, May-June, v 65, Nos 5, 6, 133-4

In 1933, the author described a phenolphthalein starch medium for rapid isolation of *V. cholerae* [this Bulletin 1934, v 31, 44]. As this liquid medium rarely yielded pure cultures although vibrium growth preponderated he has modified it to a plate medium as follows —

A mixture of 40 cc egg-white, 280 cc distilled water and 20 cc V N 10H is beaten thoroughly, boiled gently in a basin for 30 minutes and cooled to room temperature. There are then added 100 cc of 10 per cent aqueous solution of soluble starch previously warmed to 40 C and well-shaken for 2 minutes. The volume is then made up to 1 litre with distilled water. To this are added —

| | |
|--------------------|-------|
| Peptone | 10 gm |
| Meat extract | 3 gm |
| Potassium nitrate | 3 gm |
| Sodium chloride | 3 gm |
| Maltose | 1 gm |
| Magnesium chloride | 1 gm |
| Agar agar | 20 gm |

The mixture is heated with frequent shaking in a waterbath for 1 hour, filtered through cotton and adjusted to pH 8.0. The filtrate is distributed in 100 cc lots in flasks and autoclaved at 15 lb pressure for 15 minutes. Just before plates are poured 1 cc of 1/10,000 malachite green in 95 per cent alcohol and 0.5 cc of 1/100 rosolic acid in 95 per cent alcohol are added to each 100 cc of medium and shaken until the indicators are evenly distributed. The medium is poured into plates to a depth of about 0.3 cm. The surface of the cooled medium should not be excessively moist.

After 18 to 24 hours at 37°C, *V. cholerae* grows as transparent colonies with a clear greenish-yellow zone surrounding each one and standing out against the red background of the medium. This zone is due to the acid produced by the organism during fermentation of the starch. Various strains of common intestinal pathogens tested gave no such zone of discoloration. Staphylococci and enterococci were inhibited by the malachite green and rosolic acid. Mould contaminants could usually be distinguished morphologically and by their late appearance.

A total of 50 strains of *V. cholerae* gave the characteristic zone of decolorization but a laboratory strain of *Inaba* gave poor growth, owing to its sensitivity to rosolic acid, nevertheless it showed the zone of decolorization. The medium has been found of great practical use for some years in isolating *V. cholerae*.

HUANG, K W & MAO, Y C Pa-Pin (Transient Paralysis) complicating Asiatic Cholera Amer J Med Sci 1947, Aug, v 214, No 2, 153-5 [12 refs].

Pa-pin, which has been observed by the authors in 11 cases of cholera in the Chinese province of Szechuan, resembles the rare malady known as transient familial periodic paralysis. Clinical, laboratory and experimental work has pointed to barium poisoning as the cause of the malady. A further clue to the

nature of the paralysis is given in the curative action of this flaccid paralysis by administration of potassium. Although the condition is not familial in cholera nor yet a barium poisoning, it is reasonable to suppose that the pathogenesis is the same in both cases—a disturbance of potassium metabolism due to mobilization of barium from the bone reservoir as a result of dehydration and acidosis. In cholera the paralysis is late, at the time of recovery from gastro-intestinal symptoms after several days salt free diet with no drugs except non-barium containing saline infusions.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

TRANS. ROY. SOC. TROP. MED. & HYG. 1947 Sept. v 41 No 1 55-61 [35 refs.] Discussion on Amoebiasis (WENYON C. M. (President) MORGAN TROYD F. MANSON-BAHR, P. STEWART G. T. O'CONNOR, R. J. MORTON T. C. GOODWIN L. G. NAPIER, L. E. HOARE C. A. ANDREW R. R. STANKUS, H. S. JONES W. R. COOKE W. E.)

Dr C. M. WENYON in his introductory remarks pointed out that interest in the subject of amoebiasis has been stimulated by great wars. This was the case during and after the 1914-1918 and also the 1939-1945 conflicts.

In the case of amoebiasis and other infections to which a large number of susceptible individuals are exposed, it is probable that the percentage of those who become infected is actually no greater than that which occurs in times of peace. The actual numbers are, however much greater in war. It is probable also that most of the cases which appear refractory to emetine or other drugs eventually recover.

There are reasons for believing that epidemics of amoebic dysentery do not occur and reference is made to the controversial instance of the Gallipoli outbreak in 1915 and the Chicago incident of 1933-1934.

It is strange that there is such little correlation between the incidence of healthy carriers and cases of amoebic dysentery. In the tropics, cases of amoebic dysentery are commoner than in colder countries and it is well understood that healthy persons, such as soldiers going overseas, amongst whom carriers occur may develop amoebic dysentery soon after arrival in the tropics, when it is safe to assume they would not have done so if they had stayed at home.

If this is due to the original strain of *E. histolytica* then it denotes that some change in the intestinal mucosa must have taken place possibly in the nature of the bacterial flora, as in the self-conducted experiments made by WESTERLUND. From observations on human beings and monkeys, it is clear that the extent of invasion of the intestinal mucosa varies considerably and that sometimes, as in monkeys, when there is no visible macroscopic lesion, examination of sections microscopically will reveal that some invasion has taken place. The question whether *E. histolytica* can live in the large intestine of man without giving rise to lesions, however minimal cannot be answered. From his own experience Dr Wenyon brought forward evidence that amoebic infection can be present without giving rise to any recognizable disturbance, and can then disappear without treatment.

A point of interest is the significance of the small race of *E. histolytica*. It is generally agreed that two races do occur. The question of behaviour of this in the human intestine is difficult to decide as there do not appear to have been satisfactory records of frank amoebic dysentery in man caused by it so that we are left to surmise that the tendency to damage of the intestinal wall is less than in the large race.

As regards treatment of amoebic infections, Dr Wenyon drew attention once more to his work with O'CONNOR in Egypt during the 1914-1918 war, when the best results were obtained by giving each morning for 12 days one grain injection of emetine subcutaneously, and half a grain in capsules each evening by mouth.

Dr F MURGATROYD dealt first with diagnosis. In intestinal amoebiasis, direct microscopic examination of freshly-passed stools remains the basic diagnostic procedure. He had been unable to confirm the provocative action of emetine in diagnosis, upon which so much has recently been written, and suggested that those who had found it of value should publish the data on which their findings rest.

In his experience, the value of sigmoidoscopy or proctoscopy is slight, nor is X-ray examination of much assistance in diagnosis. The complement-fixation reaction is neither readily applicable nor reliable.

Reviewing the various forms of antiamoebic treatment, he pointed out that until recently emetine hydrochloride and emetine bismuth iodide were much less used in the U.S.A. than in Great Britain, and that in the latter country diodoquin was virtually unknown. The initial promise of combined treatment with emetine bismuth iodide and chiniofon retention enemata had not been sustained. On the question of the possible part played by concomitant bacteria in the syndrome, he finds it difficult to believe that penicillin and sulphonamide can make much difference to the total results of treating amoebiasis, since, in general, the cases refractory to treatment are not necessarily those with gross lesions. Retention enemata of emetine 1:30,000 produce results no different from those obtained with chiniofon.

It is interesting that when an emetine enema is evacuated after some hours it shows no amoebicidal activity. Of 45 patients given chiniofon enemata, 31 appeared cured, 3 relapsed and the fate of 11 is unknown. Of 53 given emetine enemata, 31 appeared cured, 5 relapsed and the results of 17 are unknown. It is suggested that the advantages gained by retention enemata in general are doubtful. To explain cases of amoebiasis refractory to treatment it is suggested that amoebae may vary in their resistance to the drugs employed, so that inadequate treatment may lead to drug resistance. Together with GOODWIN, Dr Murgatroyd has been able to bring forward evidence, by observations on infected rats, that emetine-resistance is indeed a reality. On drug metabolism we have little precise knowledge. In the case of emetine, the tests are insufficiently sensitive to follow the drug through the body. Speculations are based on therapeutic results. Thus the failure of emetine to cure amoebiasis in cats is attributed to rapid excretion in the urine. Save in a small percentage of human patients, emetine hydrochloride in doses of 1 grain daily appears either insufficient to maintain an amoebicidal medium in the tissues for a sufficient length of time to eradicate infection, or it fails to destroy the parasites in the lumen of the gut. This method, however, has been considered adequate by many in India.

The necessity of giving emetine bismuth iodide in a form in which it becomes dispersed in the gut is discussed. The addition of emetine hydrochloride parenterally in 'loading' doses at the beginning of treatment with E.B.I. may be reasonable.

It seems reasonable also to treat asymptomatic carriers of *E. histolytica* whenever possible. Dr Murgatroyd is convinced that many of the questions raised can be settled only by general agreement on the criteria for diagnosis and the necessity of further coordinated laboratory research.

Sir Philip MANSON-BAHR described the advantages of diagnosis by proctoscopy together with the variable appearances observed.

He believed that the biopsy pictures obtained from the mucous membrane are diagnostically important.

Radioscopy is of little practical value, save in amoebic typhilitis, where a peculiar filling defect of the caecum may sometimes be of decisive diagnostic value.

Dr G. T. STEWART described added bacterial infection in amoebiasis and post-dysenteric colitis. The problem of intestinal amoebiasis is twofold. Firstly there is straightforward amoebic infection and secondly the possibility of further infection by bacteria. Post-dysenteric colitis should be kept apart from the psychosomatic disorders which are grouped under "irritable colon".

The main qualitative alterations in the bacterial flora of the faeces in cases of diarrhoea due to active amoebiasis and post-dysenteric colitis are given in a table and compared with control cases. *Bact. coli* is equally prevalent in both groups, whilst paracolon bacilli and *Streptococcus faecalis* are more prevalent in the dysenteric group and statistical analysis suggests that the increased prevalence is unlikely to have arisen by chance.

In vitro penicillin inhibits strains of *Bact. coli*, paracolon bacilli and *S. faecalis* at concentrations ranging from 20 to 100 units per cc., but in the presence of certain sulphonamides a synergic action obtains whereby the effective bacteriostatic concentration of each drug is lowered. On this evidence, Dr Stewart has given penicillin parenterally with sulphathiazole orally to some patients and penicillin rectally to others.

Dr R. J. O'CONNOR has investigated the fate of penicillin administered rectally in treatment of amoebiasis. It was found that the first motion passed contained a large amount of penicillin at a high concentration, but subsequent motions contained little or none. The results obtained were sufficiently constant to suggest that by the rectal administration of penicillin, urinary levels of some therapeutic value might be obtained.

Air-Commodore MORROW described acute fulminating amoebic dysentery, an amoeboma simulating a neoplasm, amoebic abscess of the liver heralded by generalized urticaria, and amoebic typhilitis simulating appendicitis, with an abscess impacted in the appendix. He also outlined a course of treatment which had been found invaluable in very chronic relapsing cases. It consists of penicillin 1.5 mega units by needle + 100 gm. of sulphasuxidine for the first 3 days, followed by 1 grain of emetine for 6-10 days, the latter dosage being reserved for cases in which there is leucocytosis together with the emetine, the patient received 3 tablets t.i.d. of drodoquin for 21 days. This is followed by emetine enemas (Eli Lilly & Co.) 2 tablets of $\frac{1}{2}$ grain each t.i.d. for 10 days together with chumfon retention enema of 2½ per cent. commencing with 250 cc. and going up to 700 cc. This has proved effective in every one of his resistant war cases up to date. It has been proved conclusively by barium enema of the same consistency that with 200 cc. the splenic flexure is reached, with 500 cc. the hepatic flexure and with 700 cc. the caecum.

Mr L. G. GOODWIN showed a film recording a method of producing experimental infections with *E. histolytica* in young rats. The methods developed at the Wellcome Laboratories differ somewhat from those described by W. R. JONES [this Bulletin 1947 v. 44 313]. It has been shown that strains derived from different sources vary in their infectivity for the rat and that pathogenicity does not depend upon the number of amoebae injected, nor upon the severity of the human infections from which they were derived. It has been shown that a strain from a symptomless carrier will produce severe lesions in the rats' caecum.

Dr C. A. HOARE spoke on certain aspects of the host-parasite relationship in amoebiasis, particularly with the mode of life of *Entamoeba histolytica* in the human host. He had been able to convince himself that a certain proportion

of amoebae from cases of chronic amoebiasis have food vacuoles containing bacteria. In natural and experimental infection of macaque monkeys, *E histolytica* behaves in most cases as a true commensal, living in the lumen of the gut and feeding on bacteria and faecal debris, and in experimentally infected rats the amoebae live as commensals, ingest bacteria, invade the intestinal wall and feed on red blood corpuscles.

The views of some authors that the amoebae living in the lumen of the gut are the only forms capable of encysting and propagating the infection need verification, whilst others have found that these forms are more resistant to the action of emetine than the tissue forms.

P Manson-Bahr

NAPIER, L. E. **The Cyst-Passer** *J Trop Med & Hyg* 1947, Sept, v 50, No 9, 169-74

In an editorial article Napier discusses the significance of *Entamoeba histolytica* infections in "cyst passers". Some hold that such carriers, like diphtheria and typhoid carriers, are a menace to the community, others consider their infections invariably pathogenic, and so incompatible to perfect health in the individual, a third group regards the infection as only doubtfully pathogenic and so common that little can be done about it in practice, and a fourth believes the infection of no clinical significance if unattended by physical signs or symptoms. Stool surveys show very high rates (55.5 per cent) of infection in certain communities in the temperate and subtropical zones, and in England, some years ago, 11 per cent of a cross section of the population was found to be infected. A person may pass cysts for a year or two and then cease to do so, so the current infection-rates do not necessarily indicate the true incidence of infection in a population.

As amoebic dysentery [as opposed to amoebiasis] is essentially a tropical disease it is difficult to believe that pathological lesions are present in every case of infestation with *E histolytica*, and the evidence in support of this contention is conflicting. *E histolytica* can be cultured in the absence of mammalian cells, and so may live commensally in the gut of man. The theories put forward to account for its penetration into tissues include (1) variations between strains of parasites, (2) the need for a synergistic bacterial or virus infection, or (3) differences in the resistance or degree of immunity of individual hosts. Arguments for and against these are considered at some length, but none of them has been substantiated, these matters require reinvestigation.

If there is sound evidence that infection with *E histolytica* invariably is associated with penetration of the gut tissues, routine examination of at least all sick persons in temperate climates should be done to exclude amoebiasis, and those infected should be treated. Furthermore, cyst passers in the temperate climates should be sought out and their infections eradicated in the interests of public health. The author considers it irrational to ignore the millions passing cysts in the temperate climates while treating rigorously those few symptom-free individuals in whom the infection has casually been discovered. The convalescent cyst passer in or from the tropics he holds to constitute an entirely different problem.

A. R. D. Adams

REES, C. W., REARDON, Lucy V., JONES, Frances E. & GRIFFIN, A. M. with the technical assistance of Ida L. BARTGIS. **Observations on the Excystation of *Endamoeba histolytica*** *J Parasitology* 1947, Aug, v 33, No 4, 385

The senior author (*Amer J Trop Med* 1942, v 22: 487) reported a micro-isolation technique for obtaining bacteria-free cysts of *Entamoeba histolytica*.

Dealing with complications the author states that the clinical course of liver abscess was typical amoebic hepatitis was often atypical, with low-grade pyrexia and often normal or slightly raised leucocyte counts, while many cases diagnosed as right pleural effusion turned out to be hepatitis and responding to emetine. Two cases of perianal cutaneous amoebiasis (this must be a rare condition) confirmed microscopically responded well to the usual anti-amoebic treatment. An interesting sequelae of chronic caecal amoebiasis was found to be intestinal mal-absorption with steatorrhoea.

Treatment—Emetine has an immediate effect in most acute infections but when given alone it will not bring about a cure in most cases. It has no effect on cysts, but appears to be a specific in hepatitis. Emetine-resistant strains are possibly produced by indiscriminate use of this drug and its administration in insufficient doses.

Failure of Treatment—This may be due to —

1. Insufficient treatment Emetine requires to be supplemented by some other drug e.g. carbamone.

2. Faulty technique E.B.I. may be passed unabsorbed, owing to an insoluble coating in certain preparations the stools should become a blackish colour during treatment with this drug.

3. Retention enemata (quinoxyl, yaten etc.) containing about 2½ to 4 per cent. of the preparation, should be preceded by a wash out of about half a pint of two per cent. sodium bicarbonate solution and should consist of not more than 300 ml., given preferably by the drip method. The patient lies on his back for half an hour then on the left side for half an hour again on the back for the same period, and then on the right side for half an hour. For the remainder of the treatment (5 to 7 hours) he lies on his back.

4. Diet A well-balanced diet, with a minimum of roughage, and no alcohol should be given. In the past patients have sometimes been underfed.

5. Undiagnosed co-existing conditions, e.g. bacillary dysentery *Giardia* and *Trichomonas* infections, malaria, kala azar.

However after elimination of all possible fallacies, a proportion of patients relapse despite all treatment.

Indiscriminate repetition of periodic courses of emetine is to be deprecated and may be dangerous it may also possibly produce emetine-fast strains of *E. histolytica*.

Apacol, the Chinese Ya Tan Tsu, diodoquin (containing 60 per cent. iodine) have all been claimed to have had successes.

Follow-up Procedures —

1. Examination of at least 6 stools, three after administration of magnesium sulphate. Sigmoidoscopy and microscopic examination of specimens taken directly from suspicious areas.

2. Stool examinations as (1) after one month. Sigmoidoscopy if indicated.

3. Stool and general examination three months after stoppage of treatment.

[On page 180 the statement is made that emetine is made ineffective by heat sterilization. Many authorities will not agree with this observation.]

C. F. Shelton

PARKINSON T. Amoebiasis in Ceylon. *Lancet*. 1947 Oct. 23 612-15.

The object of this paper is to show how high is the incidence of amoebiasis in Ceylon.

The total admissions to the medical wards of an R.A.F. mobile field hospital between October 1944 and September 1945 were 635 of these 191 were for dysenteric disorders, as shown —

| | | |
|------------------------------------|----|------------------|
| <i>Amoebic group</i> | 97 | (50.8 per cent) |
| Primary acute amoebic dysentery | 62 | |
| Acute relapse of amoebic dysentery | 9 | |
| Chronic intestinal amoebiasis | 15 | |
| Amoebic hepatitis | 9 | |
| Liver abscess | 2 | |
| <i>Bacillary Dysentery</i> | 15 | (7.9 per cent) |
| Cholical dysentery | 14 | (7.3 per cent) |
| Non specific diarrhoea | 63 | (32.9 per cent.) |
| Lambliasis | 2 | (1.1 per cent) |

The reason for the relatively low incidence of bacillary dysentery is attributed to the fact that there was no epidemic, probably because the fly menace was avoided by DDT and the high standard of hygiene.

It is believed that half the patients admitted to hospital with diarrhoea had amoebic dysentery.

The efficacy of sulphonamides in the treatment of bacillary dysentery is such that it became customary to use these drugs as a therapeutic diagnostic test, but this approach is fallacious, as the author's observations on selected cases show that sulphonamides at least mask the symptoms of acute amoebiasis and may have some amoebicidal action. It is suggested that secondary bacterial infection of the bowel may precipitate an acute attack of amoebic dysentery and be responsible for chronicity of other cases, but the rapid disappearance of *E. histolytica* from the stools in 5 cases suggests that these drugs are lethal to the amoebae. Thereafter it was customary to use a short course of chemotherapy together with emetine as initial treatment in acute amoebiasis. The following course was adopted —

| | |
|------------|---|
| Days 1-10 | Emetine 1 grain |
| Days 1-3 | Sulphapyridine (or sulphathiazole) total 14-20 gm |
| Days 4-13 | Carbarsone 4 grains b d |
| Days 14-20 | Rest |
| Days 21-30 | E B I 1-3 grains nightly (according to tolerance) |

Forty-two patients with acute amoebiasis were treated on these lines. Of these it was possible to follow up 15 at an interval of 2 to 4 months after discharge from hospital. The results, both immediate and remote, have been impressive.

It is generally accepted that a leucocytosis is a distinctive feature of amoebic hepatitis, but only 5 out of 10 patients with this condition had a count of over 10,000 and others showed a moderate leucopenia. Only 6 gave a previous history of diarrhoea and in 5 of the 10 no *E. histolytica* or cysts were found in the stools.

LEBON, J. MAIRE, R., DUBOUCHER, G. & CLAUDE R. Amibiase intestinale récidivante traitée par l'association pénicilline, sulfaguandine et émétine [Relapsing Amoebic Dysentery treated with a Combination of Penicillin, Sulphaguanidine and Emetine] *Algérie Méd.* 1947 Aug-Sept, No 7, 562-4

Account of a case

MANSON-BAHR, P. Amoebic Abscess of the Spleen *J. Trop. Med. & Hyg.* 1947, Sept, v 50, No 9, 174-5

Generally speaking, abscesses of the spleen are extremely rare, and when they occur they are usually associated with bacterial infections.

Amoebic abscess of the spleen is of extreme rarity, and the author has been able to find but a few references to it in the literature, although most text books

refer to it. Among others, MAXWELL (*The Diseases of China* 1929 Shanghai) describes six cases in Formosa, and FRANK [this *Bulletin* 1944 v 41 572] describes one in an Indian girl.

In December 1948 the present author saw an officer from Burma, who had been invalided a year previously after 20 years service during the last 11 of which he had suffered from a marked splenomegaly believed to be malarial in origin. In 1942, in Burma, he began to suffer from increasing splenic pain. On his return to England, an abscess commenced to point in the abdominal wall in the left hypochondrium this was opened and the sinus healed spontaneously. In November 1948 the sinus reopened and discharged "anchovy-sauce" material. The spleen edge was hard and extended 4 inches below the costal margin the sinus was found to extend $9\frac{1}{2}$ inches towards the centre of the spleen. The patient was generally in good condition without fever.

Microscopically the discharge closely resembled liver pus but no *Entamoeba histolytica* were found in it, nor were cysts demonstrated in the stools there was a leucocytosis of 10,800 per cmm. X-ray examination showed slight enlargement of the liver shadow and some elevation of the diaphragmatic dome. The left lobe of the liver was not obviously altered. No connexion with the spleen was demonstrated by lipodol injection of the sinus, a few streptococci were found in the pus from the sinus, but penicillin injections were without effect.

Emetine injections were given and the sinus began to diminish simultaneously the bulk of the spleen became progressively smaller on emetine bismuth iodide within a month the spleen was no longer palpable. The patient remains in excellent health.

While the aetiological agent was not demonstrated, the history and the rapid response of the abscess to anti-amoebic therapy seem to provide conclusive evidence that this was a genuine example of an amoebic abscess of the spleen.

H. J. O'D. Burke-Gaffney

SITKH SHIM M. Balantidial Dysentery in Rodriguez and its Treatment with Mercury Bismiodide. *Brit. Med. J.* 1947 Sept. 13 417-18.

The paper describes ten cases of balantidial dysentery in Rodriguez an island 350 miles from Mauritius. Seven of the cases were in children from 3 to 13 years of age and three were in adults 30, 40 and 63 years of age. One patient a man aged 30 was treated with mepacrine and a mixture of bismuth and opium. His condition did not improve and he died five days later. All the other patients were treated with bismiodide of mercury (1/24 to $\frac{1}{4}$ grain) administered intramuscularly. Two or more injections were given and in all cases a cure was obtained. The island is 40 square miles and has a population of 12,000 every household breeds at least one pig and as the hygienic conditions are unsatisfactory balantidial dysentery is to be expected. C. M. Wrayson

CAMPKINS, V. N. & MILLER, J. H. Staining Intestinal Protozoa with Iron-Haematoxylin-Phosphotungstic Acid. *Amer. J. Clin. Path.* 1947 v 17 733-8. [Abstract by the authors]

A modification of Hendenhain's iron-haematoxylin method of staining intestinal protozoa is presented. The basic change is the application of 2 per cent. phosphotungstic acid for differentiation. This differentiator is automatic and

self-limiting requiring no microscopic control Uniform permanent film preparations of fecal specimens may be obtained rapidly by the modified procedure even by persons of limited experience "

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

KAMAL, A M, ANWAR, M, ABDEL MESSIH, G & KOLTA, Z *Louse-borne Relapsing Fever in Egypt A Review of 9,977 Cases* *J Egyptian Pub Health Ass* 1947, Jan, v 22, No 1, 1-22, 1 chart

The authors attempt to summarize the history of louse-borne relapsing fever in Egypt, which was first definitely recorded in the country by Sandwith and Engel in 1884, although it was probably seen by the doctors accompanying Napoleon when he invaded Egypt

The yearly incidence of the disease from 1906 to 1946 is given in tabular form For the first ten years, a few hundred cases occurred in most years and then from 1916 to 1920 there was an epidemic involving nearly 40,000 cases, after which the incidence rapidly declined and only 8 cases were recorded between 1926 and October 1944 At the end of 1944, there were 10 cases, in 1945, 18,277, and in 1946 up to September, 108,882 cases, with 2,367 deaths This great epidemic started in the Beni-Suef Province, and during 1945 spread to every part of the country except Aswan and Damietta In April 1946, the number of cases reached its peak, after which it declined and during the week ending September 30th only 25 cases were recorded

The authors compare the incidence of relapsing fever with that of the other prevalent louse-borne disease—typhus—and remark that this infection spreads more readily than relapsing fever among the inhabitants of the Delta Moreover, typhus remains endemic in the country, whilst relapsing fever disappears after each epidemic Of 9,977 cases, 6,596 were males and 3,381 females

A total of 3,011 cases were treated with one injection of arsphenamine The dose for adults was 0.60 gm given intravenously, and for children the dose was reduced according to age Of these 3,011 treated cases, 623 relapsed, whilst of 1,623 untreated cases, 1,182 relapsed Most of the relapses occurred before the 11th day of convalescence and the authors consider that patients should not be discharged until after 14 days' apyrexia from the first attack

A group of 365 cases was treated with two doses of arsphenamine on two consecutive days, and 39 relapsed Mapharside, injected for three consecutive days, was used for 371 cases and gave 27 relapses, but apart from the disadvantage of delaying the appearance of these relapses, there were other objections to its use, as it was very painful on injection, and induced rigors and vomiting

The effect of treatment on the case fatality rate is indicated in the following table —

| | No. of cases | Fatality rate per cent |
|-------------------------------|--------------|------------------------|
| Untreated | 245 | 4.5 |
| Treated—Arsphenamine (1 inj.) | 180 | 3.3 |
| (2 inj.) | 107 | 1.9 |
| Mapharside | 124 | 0.9 |

GARNHAM P. C. C., DAVIES, C. W., HIRSCH R. B. & THOMAS G. L. An Epidemic of Louse-borne Relapsing Fever in Kenya. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1947 Sept., v. 41 No. 1 141-70 9 figs. (2 on 1 pl.) (37 refs.)

An interesting account of the first epidemic of louse-borne relapsing fever to have been recorded in East Africa. [This disease however is well known in Abyssinia and the Sudan.]

The epidemic was introduced into Kenya from South Arabia in February 1945 when a number of Arab dhows arrived at Mombasa with cases on board. It gradually spread and by October had reached epidemic proportions. In all there were about 2,000 cases in a population of 110,000 and the mortality in untreated cases was 40 per cent.

Various control measures, including the disinfection of about 100,000 people by dusting with 5 per cent. DDT powder rapidly terminated the epidemic.

The clinical features were fairly typical, but the cases were characterized by the prominence of neurological symptoms, cardiac involvement positive Weil-Felix and negative Kahn reactions. Blood examined during the initial attack nearly always showed spirochaetes, but during relapses they were often absent or very scanty.

Lice collected from patients with spirochaetes in their blood were examined both macroscopically and by inoculation into animals, but gave uniformly negative results. Subsequently lice were kept alive for 13 days after being collected in these spirochaetes were found in large numbers and infection was produced by inoculation into monkeys. No *Ornithodoros* was ever found, and bugs collected from infected huts were negative. Attempts were made without success to transmit the infection by *Ornithodoros mombasa* and *O. sergenti*.

Rabbits, guinea-pigs, bush-babers (*Galago crassicaudatus*), white rats, white mice, gerbils and 5 species of African monkeys, were infected experimentally and showed this order of susceptibility: rabbits being the least and monkeys the most susceptible. Repeated passage in mice was easily maintained. Neurotropism hardly ever occurred.

The infections in lice showed a well-marked negative phase lasting till the 16th day and lice collected from patients and examined within 24 hours never showed spirochaetes. In view of the different results recorded in Abyssinia and China it is suggested that louse-borne spirochaetes may be divided into two groups: the first with a long negative phase in the louse including the European, North African and Abyssinian strains, and the second without this phase spirochaetes being continually present throughout the louse cycle as in the Abyssinian and Chinese strains.

No cross immunity could be detected between *S. recurrentis* and *S. duttoni* in mice and rats but a relatively refractory bush-baby was immune to *S. duttoni* after recovery from *S. recurrentis*.

Auto-agglutination of spirochaetes in old infections occurred in monkeys but not in rats. The pathogenicity of the Kenya strain in man and animals was found to resemble most closely that of *S. carteri* and differed markedly from the Chinese and Abyssinian strains. The pathological changes resembled those previously described except that in three cases degeneration of ganglion cells was found in the cerebellum without meningo-vascular inflammation.

YAWS

LOPES, C F Contribuição ao estudo da lesão primaria da boubá. Nota
previa [A Preliminary Note on the Primary Lesion of Yaws.] *Hospital*
Rio de Janeiro 1945, Dec v 28, No 6 987-97, 9 figs English summary

The author believes that the primary lesion of yaws may be distinguished readily from the secondary. It is usually larger flatter, situated below the knees and causes a definite lymph gland reaction. The affected gland is slightly painful, may enlarge to the size of a pigeon's egg, but does not suppurate.

The author considers one feature to be characteristic of the primary lesion: this is a whitish areola around the lesion, in which the skin is dry rough, keratotic and furfuraceous. This areola is of variable size, may be circinate, and is seen on only one side of the lesion, "like a diadem".

He has seen this areola in about one-third of his patients with the primary lesion, but never in the secondary. The histopathological study of this feature will be the subject of another publication.

The paper is illustrated with nine photographs of lesions.

DWINELLE, J H, SHELDON, A J, REIN, C R & STERNBERG, T H Evaluation
of Penicillin in the Treatment of Yaws. Final Report. *Amer J Trop*
Med 1947, Sept, v 27, No 5 633-41

The authors report observations made up to 12 months after treatment with penicillin of 500 cases of primary and secondary yaws in Haiti. The schedules were: 1,200,000 units of penicillin sodium in water intramuscularly in 4 days (Series A); the same total dosage of penicillin in arachis oil and 18 per cent beeswax (300,000 units of penicillin calcium per cc) in two injections, 24 hours apart (Series B); and the same schedule as B, but 10-12 hours apart (Series C). In series B and C, dosages for children were graded down. The preliminary report has been reviewed in this *Bulletin*, 1946, v 43, 1043, where the composition of the series treated was tabulated. No severe reactions were observed, but about half of the patients in Series A had pyrexia up to 100-104°F (37.5-40°C), coming on 2-8 hours after treatment started, and lasting 10-12 hours.

Results were grouped under the following headings — "Apparent cure," with clinical cure and persistent negative Kahn tests; "Satisfactory progress," with clinical cure but progressive reduction of Kahn titre to a persistent low level, but never becoming negative; and "Unsatisfactory progress" which included "reinfections," "clinical relapse" and "serological relapse."

Patients in Series A were observed every month and those in Series B and C at intervals of 3 months. The results are shown in the following table, taken from the article —

Primary and Secondary Yaws treated with 1,200,000 units Penicillin intramuscularly

| Series A 30 000 units in water 3-hourly for 4 days | Period of observation in months | | | | Total Number of patients | Percent of total |
|--|------------------------------------|-----|-----|-------|-----------------------------------|---------------------|
| | 0-3 | 4-6 | 7-9 | 10-12 | | |
| Apparent cure (1) | 0 | 0 | 5 | 47 | 52 | 28.7 |
| Satisfactory progress (2) | 5 | 5 | 7 | 106 | 123 | 65.5 |
| (1) + (2) | 5 | 5 | 12 | 153 | 175 | 90.2 |
| Unsatisfactory progress | 0 | 1 | 2 | 15 | 19 | 9.8 |
| Total | 5 | 6 | 15 | 168 | 194 | |
| <hr/> | | | | | | |
| Series B In arachis oil and beeswax in 2 doses 24 hours apart | 3 | 6 | 9 | 12 | | |
| Apparent cure (1) | 0 | 1 | 3 | 10 | 14 | 11.0 |
| Satisfactory progress (2) | 14 | 5 | 17 | 65 | 104 | 81.9 |
| (1) + (2) | 14 | 6 | 20 | 75 | 113 | 92.9 |
| Unsatisfactory progress | 0 | 1 | 5 | 3 | 9 | 7.1 |
| Total | 14 | 10 | 25 | 78 | 127 | |
| <hr/> | | | | | | |
| Series C In arachis oil and beeswax in 2 doses 10-12 hours apart | 3 | 6 | 9 | 12 | | |
| Apparent cure (1) | 0 | 0 | 1 | 7 | 8 | 6.4 |
| Satisfactory progress (2) | 13 | 10 | 23 | 62 | 108 | 86.4 |
| (1) + (2) | 13 | 10 | 24 | 69 | 116 | 92.8 |
| Unsatisfactory progress | 1 | 1 | | 5 | 9 | 7.2 |
| Total | 14 | 11 | 28 | 74 | 125 | |

The higher percentage (28.7) of serological ("apparent cure") cases in Series A after 12 months may be due to the longer course (4 days) of treatment or to a change in the composition of penicillin which occurred in 1945 between the treatment of Series A and Series B and C. This is balanced by the higher percentage of satisfactory progress cases in Series B and C so that the percentages of Apparent cure and Satisfactory progress together in each Series is approximately the same i.e. 90-93. Since in Series A, children received the same dose as adults with no difference in serological response from them, it is suggested that the amount of penicillin beyond a certain minimum was not the essential factor in producing serological reversals. Duration of infection also apparently had no effect on the response to penicillin.

Of the Unsatisfactory progress cases (8.3 per cent.) at the end of 12 months in Series A, B and C respectively. Reinfection had occurred in 3.1, 1.8 and 2.4 per cent. Clinical relapses in 0.2, 4 and 0.6 per cent. and "Serological relapses" in 6.7, 3.1 and 4.0 per cent. Surprisingly few patients

were reinfected, 2 per cent of all the series combined, in about half of these, the Kahn titre had increased 1-2 months before the "Reinfection". Only 0.9 per cent of the series combined were "Clinical relapses". "Serological relapses" comprised 4.9 per cent.

The authors regard penicillin as the present-day drug of choice in the treatment of yaws, particularly the arachis oil and beeswax preparation, because of the short course needed and the great reduction in cases of reinfection. It should rapidly bring yaws under control.

[Even if half the "Reinfections" are included in the "Clinical relapses," their low incidence suggests that the low Kahn titres of the "satisfactory progress" cases might, for practical purposes, be regarded as negatives. As the authors observe, longer observation might support this.]

TURNER, T. B., McLEOD, Charlotte & UPDYKE, Elaine L. **Cross Immunity in Experimental Syphilis, Yaws, and Venereal Spirochaetosis of Rabbits**
Amer J Hyg 1947, Sept, v 46, No 2, 287-95

Batches of 10-20 rabbits were inoculated intra-testicularly with *Treponema pallidum* (syphilis), *Trep. pertenue* (yaws) and *Trep. cuniculi* (venereal spirochaetosis of rabbits) respectively. Six months later they were inoculated intracutaneously with different strains of the same three species of treponema so that all possible cross-immunities could be observed. Results were compared with controls. Observations were made 21 and 35 days after the second inoculations. The tables show that there was considerable cross-immunity between all three species, perhaps less between syphilis or yaws and *cuniculi* infection than between yaws and syphilis. The protection of one infection against another is probably greater than the figures indicate, since the challenge doses were many thousands of times larger than those probably necessary to cause infection in unprotected rabbits.

It is pointed out that, in experimental syphilis, immunity is of three grades, permitting, (a) symptomatic reinfection, (b) asymptomatic reinfection, or (c) no reinfection. It depends in part upon the resistance which the host has already developed and also upon the size of the challenge dose. Although it would be unwise to carry the results of experimental work on animals into the epidemiology of yaws and syphilis in man "nevertheless, the experimental results are entirely consistent with the other evidence of a clinical, epidemiological and experimental nature, which indicates that a serviceable degree of reciprocal immunity exists between yaws and syphilis as they occur in nature." Although there is little information regarding the minimal infective doses of yaws and syphilitic treponemata for man, under natural conditions doses would probably be small so that a relatively low immunity might often protect.

An anti-yaws and anti-syphilis measure in man worthy of closer investigation might be the protection affected by *Trep. cuniculi* infection. In the authors' laboratories "at times both yaws and *cuniculi* spirochaetes produce lesions which exhibit in the experimental animal many of the characteristics of syphilitic lesions, but we have never been able to establish that this altered response signified a permanent change in any particular strain of yaws or *cuniculi* spirochaete." There is no evidence, within historical times, that syphilis has derived from yaws or *vice versa*. Perhaps, in fact, one or both of them originated from venereal spirochaetosis of rabbits or *vice versa*. *T. cuniculi* is believed to be non-pathogenic for man, but further study is needed.

Resistance of *Y. pseudotuberculosis* to challenge inoculation of heterologous strains of *T. pallidum*, *T. pertenue* and *T. cuniculi* 6 months after original inoculation. Results 31 days after challenge inoculation

LEPROSY

MOISER, B Hansen's Disease (Leprosy) and Cockroaches *East African Med J* 1947, June, v 24, No 6, 230-36, 2 diagrams

This paper deals with zoological facts regarding cockroaches. The author admits that he had never seen these insects bite man, and failed to get them to do so in daylight, but he accepts statements of others to the effect that they bite at night. They are especially numerous in damp hot climates. In African huts, spraying with 5 per cent DDT in kerosene kills them in a dosage of a gallon per 100 sq feet, but the eggs are protected by a chitinous envelope, the cycle from the ova through four or more nymphal stages to adults occupies a year. A detailed description is given of the anatomy of cockroaches and it is stated that the wounds made by the chitinous mouth parts as a result of biting are characteristic, being circular or oval and varying from the size of a pin's head to 4 or 5 mm in diameter. A method of dissecting the insects is given and the appearances of acid-fast bacilli in their gut are described as in previous papers by the same author [this *Bulletin*, 1947, v 44, 725]. The occurrence of *Spirochaeta recurrentis* and *Rickettsia* in these insects is referred to, as well as helminths and certain pathogenic bacteria. L Rogers

ZANETTI, V Coloration en serie du bacille de Hansen et dépistage des lépreux bacillaires [Staining of Leprosy Bacilli and Diagnosis of Leprosy] *Ann Soc Belge de Méd Trop* 1947, Mar 31, v 27, No 1, 179-86

This paper deals with the following modification of the carbol-fuchsin method of staining lepra bacilli. First fix by heat and stain for 20 minutes with a cold solution consisting of 1 gm fuchsin, 10 cc 95 per cent alcohol, 5 cc crystallized phenol, made up to 100 cc with distilled water. Wash quickly and decolorize for 7 minutes in 0.5 per cent solution of sulphuric acid. Counterstain for one minute with a solution consisting of 0.15 gm toluidine blue, 10 cc 95 per cent alcohol, 3 gm crystallized phenol, made up to 100 cc with distilled water. Wash and dry. The bacilli are stained red with a background of violet. The acid-fast bacilli are estimated in fifty fields in five specimens taken respectively from the ear, the forehead, the cheek, a leprous plaque and from healthy skin.

The results of 2,620 such examinations are discussed. In 252 of these, clumps of bacilli were found in variable numbers in lepromatous cases. The negative cases were clinically of the nerve type, a few reacting cases of which were positive. Repeated examinations show that when very few bacilli are present they tend to disappear under treatment in four to six months, but in a few cases they increase in numbers with passage of the case into the lepromatous type. In the 252 positive cases showing clumps of bacilli, they were only found in the ears in 73, or 28.97 per cent, in both the ears and other parts in 134, or 53.17 per cent, and in the remaining 45, or 17.86 per cent, in other places only. The ear is the site of election for bacteriological examinations. This method gave better results than are obtained by hot solutions of carbol fuchsin and as good as those obtained by Hallberg's method [this *Bulletin*, 1947, v 44, 591]. L Rogers

SILVA, G Resultados de pruebas tuberculinicas en hijos de leprosos del preventivo "Amparo Santa Cruz" de Porto Alegre (Brasil) [Tuberculin Tests in the Children of Leprosy Patients in the Amparo Santa Cruz (Brazil)] *Hospital Rio de Janeiro* 1947, Aug, v 32, No 2, 163-4

The English summary appended to the paper is as follows —

"1 The tuberculin index of 121 children born from leper parents present values comparable to those of other human groups at the same ages (58.4 per

100 reactors in lepers sons and 52.9 per 100 reactors in children of an orphan asylum).

2. In 42 lepers sons non reactors to the tuberculin test, the Mitsuda reaction (lepromin reaction) was positive in 82.8 per 100.

SCHUJMAN S. El valor del chanmoogra en el tratamiento de la lepra. I. Diferente evolución de los casos de lepra tuberculoides en los adultos tratados y no tratados con la medicación chanmoogrica. [The Value of Chanmoogra in the Treatment of Leprosy. Course of Tuberculoid Leprosy in Adults.] *Prensa Méd. Argentina*. 1947 July 4 v 34 No. 27 1215-25 9 figs. [17 refs.] English summary

Some practitioners speak of chanmoogra with enthusiasm as to its success in the treatment of leprosy others equally detractingly of it. This divergence is explained says the author by their referring to different forms of the disease the former to the benign tuberculoid type the latter to the malignant lepromatous type.

The present article is concerned with the tuberculoid form. In infants so affected, but left untreated there is an early and spontaneous reaction against it and retrogression takes place. This is not so with adults. The author bases his conclusions on more than 400 cases seen during a period of 17 years. If untreated the primary lesion extends and secondary lesions appear or more rarely the condition remains stationary it does not clear up. If the primary lesion is excised, but no other treatment adopted, recurrence *in situ* follows. If chanmoogra is given in small doses i.e. inadequately gradual retrogression is observed, as one would expect similarly if treatment is abandoned when initial improvement occurs.

HELMINTHIASIS

KHAW O K. An Investigation on Schistosomiasis. *Chinese Med. J. Shanghai*. 1947 May-June v 65 Nos. 5/8 129-32.

An investigation on the possibility of schistosomiasis being introduced into India by West African troops who were infected with *S. haematobium mansoni* [presumably *S. mansoni*] and *S. haematobium* revealed —

- a. That there were no known snail hosts of the parasites in India.
- b. That there was no infection of the local snails nor could they be experimentally infected under field conditions.
- c. That there were no cases of the disease among the indigenous population amongst whom the West Africans had lived in intimate contact, and using in common the same sources of fresh water stocked with gastropod molluscs.

[See this *Bulletin* 1947 v 44 599 but also 1945 v 42, 742.]

BOSCARDI F. Studi sullo sviluppo e sulla struttura di *Schistosoma haematobium* nel mollusco ospite intermedio. [The Development and Structure of *Schistosoma haematobium* in its Molluscan Host.] *Riv. di Parasit. Rome*. 1947 June-Sept v 8, Nos. 2/3 67-83 10 figs. English summary

This article will interest helminthologists who wish for information on the life-history of *Sch. haematobium* and in the pathological changes which its presence and growth cause in *Bul.* and *Phys.*. The article is crammed with detail and to grasp these the original must be referred to but the findings may be summarized. Serial sections made soon after the miracidium enters

the mollusc show that penetration does not take place by the skin but by the mouth, the primary sporocyst develops and invasion of the tissues takes place and in the daughter-cysts the forked cercariae develop. Only one miracidium develops in a snail, some sort of immunity seems to prevent invasion by a second miracidium. Photomicrographs are clearly reproduced illustrating the development of the parasite and the tissue changes set up in the snail host.

BOIRON, H. & KOERBER, R. Contribution à l'étude de la bilharziose urinaire en Afrique occidentale française [Urinary Schistosomiasis in French West Africa] *Bull Soc Path Exot* 1947, v 40, Nos 3/4, 118-24 [13 refs]

The authors briefly review some of the work done since 1905 in French West Africa, on urinary schistosomiasis. After quoting a series of figures, they conclude that the most active foci of this disease are round Dakar, Kaolack and Fatick in Senegal, the forest region of French Guinea, the Saharan and Soudan regions of Niger, the coastal area of Dahomey, the Ivory Coast, and the basin of the Volta in the French Soudan. They mention particularly 5 foci, after noting that the disease is found along the chief water routes, whereas the coastal areas (except Dakar) are less affected. These foci are—(1) Along the Niger and its tributaries (Milo, Baoulé and Bagoé) from its source to Timbuktu (2) The old focus in Haute-Volta, associated with the Volta and its tributaries (3) The river Senegal and its tributaries (4) The rivers Gambia, Casamance and Saloum (5) Dakar. They also mention foci in contiguous areas of the British territories of the Gambia and the Gold Coast.

The authors themselves examined 580 schoolboys at Medina and 3,160 soldiers of the garrison of Dakar. In the former, 14.8 per cent showed haematuria, and in 6 per cent eggs of *Schistosoma haematobium* were found. Eggs were also found at a single examination in 13 per cent of the soldiers indigenous to French West Africa—lower rates were found in a few from the Cameroons and in 422 who originated from Madagascar. The authors, however, think that 15 and 20 per cent respectively would probably more correctly represent the incidence in the schoolboys and the local troops, arguing that a single examination cannot reveal all cases.

The authors discuss briefly some aspects of the pathology of schistosomiasis, concluding that in West Africa this disease cannot be regarded as a factor in the incidence of primary cancer of the liver. They have used intramuscular pentamidine in treatment of a few cases, with apparent success, but they have not been able to keep under observation for more than a short time the 15 patients so treated.

Charles Wilcocks

VOGEL, H. Hermaphrodites of *Schistosoma mansoni*. *Ann Trop Med & Parasit* 1947, Sept, v 41, No 2, 266-77, 6 figs

The author describes bisexual males of *S. mansoni*, recovered from infected laboratory animals. These worms, in addition to showing the ordinary characters of males, were provided with an ovary which, when well-developed, contained typical egg-cells. In some, a well-defined oviduct and a uterus were present, although a female genital pore could never be clearly seen. The author notes that these hermaphrodites tend to occur in less suitable hosts, such as guinea-pigs and rabbits, but not in the recognized "good hosts" such as man and monkey, and only rarely in mice; on the other hand, they occurred frequently in hamsters, which are regarded as suitable hosts in every respect. The scarcity of female worms in guinea-pigs containing hermaphrodites suggested that the absence of the female partner might be another factor in causing the development of female organs in the male.

100 reactors in lepers sons and 52.9 per 100 reactors in children of an orphan asylum).

2. In 42 lepers sons non reactors to the tuberculin test, the Mitsuda reaction (lepromin reaction) was positive in 92.8 per 100.

SCHUJMAN S. El valor del chaulmoogra en el tratamiento de la lepra. I. Diferente evolución de los casos de lepra tuberculóide en los adultos tratados y no tratados con la medicación chaulmoogrica. [The Value of Chaulmoogra in the Treatment of Leprosy Course of Tuberculoid Leprosy in Adults.] *Revista Méd. Argentina* 1947 July 4 v 34 No. 27 1215-25 9 figs. [17 refs.] English summary

Some practitioners speak of chaulmoogra with enthusiasm as to its success in the treatment of leprosy others equally detractingly of it. This divergence is explained, says the author by their referring to different forms of the disease the former to the benign tuberculoid type, the latter to the malignant lepromatous type.

The present article is concerned with the tuberculoid form. In infants so affected, but left untreated, there is an early and spontaneous reaction against it and retrogression takes place. An investigation on the possibility of schistosomiasis being introduced into India by West African troops who were infected with *S. haematobium* mansoni [presumably *S. mansoni*] and *S. haematobium* revealed —

- a. That there were no known snail hosts of the parasites in India.
 - b. That there was no infection of the local snails nor could they be experimentally infected under field conditions.
 - c. That there were no cases of the disease among the indigenous population amongst whom the West Africans had lived in intimate contact, and using in common the same sources of fresh water stocked with gastropod molluscs.
- [See this *Bulletin* 1947 44 599 but also 1945 42, 742.]

BOSCARDI F. Studi sullo sviluppo e sulla struttura di *Schistosoma haematobium* nel mollusco ospite intermedio. [The Development and Structure of *Schistosoma haematobium* in its Molluscan Host.] *Riv. di Parasit. Rome*. 1947 June-Sept v 8 Nos. 2/3 67-83 10 figs. English summary

This article will interest helminthologist who wish for information on the life-history of *Sch. haematobium* and in the pathological changes which its presence and growth cause in *Bulimus* and *Physastra*. The article is crammed with detail and to grasp these the original must be referred to but the findings may be summarized. Serial sections made soon after the miracidium enters

the mollusc show that penetration does not take place by the skin but by the mouth, the primary sporocyst develops and invasion of the tissues takes place and in the daughter-cysts the forked cercariae develop. Only one miracidium develops in a snail, some sort of immunity seems to prevent invasion by a second miracidium. Photomicrographs are clearly reproduced illustrating the development of the parasite and the tissue changes set up in the snail host.

BOIRON, H & KOERBER, R Contribution à l'étude de la bilharziose urinaire en Afrique occidentale française [Urinary Schistosomiasis in French West Africa] *Bull Soc Path Exot* 1947, v 40, Nos 3/4, 118-24 [13 refs]

The authors briefly review some of the work done since 1905 in French West Africa, on urinary schistosomiasis. After quoting a series of figures, they conclude that the most active foci of this disease are round Dakar, Kaolack and Fatick in Senegal, the forest region of French Guinea, the Saharan and Soudan regions of Niger, the coastal area of Dahomey, the Ivory Coast, and the basin of the Volta in the French Soudan. They mention particularly 5 foci, after noting that the disease is found along the chief water routes, whereas the coastal areas (except Dakar) are less affected. These foci are—(1) Along the Niger and its tributaries (Milo, Baoule and Bagoé) from its source to Timbuktu. (2) The old focus in Haute-Volta, associated with the Volta and its tributaries. (3) The river Senegal and its tributaries. (4) The rivers Gambia, Casamance and Saloum. (5) Dakar. They also mention foci in contiguous areas of the British territories of the Gambia and the Gold Coast.

The authors themselves examined 580 schoolboys at Médina and 3,160 soldiers of the garrison of Dakar. In the former, 14.8 per cent showed haematuria, and in 6 per cent eggs of *Schistosoma haematobium* were found. Eggs were also found at a single examination in 13 per cent of the soldiers indigenous to French West Africa—lower rates were found in a few from the Cameroons and in 422 who originated from Madagascar. The authors, however, think that 15 and 20 per cent respectively would probably more correctly represent the incidence in the schoolboys and the local troops, arguing that a single examination cannot reveal all cases.

The authors discuss briefly some aspects of the pathology of schistosomiasis, concluding that in West Africa this disease cannot be regarded as a factor in the incidence of primary cancer of the liver. They have used intramuscular pentamidine in treatment of a few cases, with apparent success, but they have not been able to keep under observation for more than a short time the 15 patients so treated.

Charles Wilcocks

VOGEL, H Hermaphrodites of *Schistosoma mansoni* *Ann Trop Med & Parasit* 1947, Sept, v 41, No 2, 266-77, 6 figs

The author describes bisexual males of *S. mansoni*, recovered from infected laboratory animals. These worms, in addition to showing the ordinary characters of males, were provided with an ovary which, when well developed, contained typical egg-cells, in some, a well-defined oviduct and a uterus were present, although a female genital pore could never be clearly seen. The author notes that these hermaphrodites tend to occur in less suitable hosts, such as guinea-pigs and rabbits, but not in the recognized "good hosts" such as man and monkey, and only rarely in mice. On the other hand, they occurred frequently in hamsters, which are regarded as suitable hosts in every respect. The scarcity of female worms in guinea-pigs containing hermaphrodites suggested that the absence of the female partner might be another factor in causing the development of female organs in the male.

In order to test this theory a number of guinea-pigs, hamsters, and mice, were exposed to male cercariae only control animals simultaneously infected with both sexes of cercariae being kept for comparison. The results of these experiments were as follows—Two guinea-pigs infected with both sexes yielded 70 male worms, of which three (4.3 per cent.) were provided with a female germ-gland, whereas two guinea-pigs infected with male cercariae only yielded 83 males of which 36 (43.4 per cent.) contained an ovary. Hamsters infected in the same manner yielded similar results thus four hamsters exposed to cercariae of both sexes were subsequently found to harbour 51 male *S. mansoni* of which only one was an hermaphrodite while in contrast to these findings two hamsters exposed to male cercariae only were found to harbour 92 male worms, of which 37 (40.2 per cent.) possessed an ovary. Mice used as hosts gave quite different results, for out of 56 male worms recovered from bi-sexually infected mice, 1.9 per cent. showed an ovary whilst amongst 247 males from mice exposed exclusively to male cercariae, a smaller proportion, 1.2 per cent. were hermaphrodites.

Vogel, having shown that the appearance of female characters in the male worm is associated with development in an unsuitable host in the case of guinea-pigs and is stimulated by the absence of the female partner in the case of guinea-pigs and hamsters then discusses the causal explanation for the phenomenon. GIOVANKOLA [this *Bulletin* 1938 v 33 955] records the finding in a rabbit previously exposed to male cercariae only of three pairs of *S. mansoni* in copula each pair consisting of two males. The author of the present paper records similar findings at autopsies on animals infected by him with male cercariae and notes that in such instances the large worms, which play the part of the male partner contain only male genital organs, whereas the small embraced males are hermaphrodites. In view of these findings, he suggests the possibility that residence in the gynaeceophoric canal, which is essential to sexual maturation of the female may likewise stimulate the development of rudimentary female characters in the male. R. M. Gordon

MORRIS L. Fistules à distance et indurations fécales. Séquelles de bilharziose intestinale. [Fistulae and Induration of the Buttocks after Intestinal Schistosomiasis.] *Bull Soc Path. Exot* 1947 v 40 Nos 3/4 88-8.

The author describes a patient who suffered for many years from a series of fistulae [sinuses might be a more accurate word] which developed on the buttocks and on the posterior surfaces of the thighs. The cause of these was obscure but in 1936 some years after the sinuses had first begun to appear eggs of *Schistosoma mansoni* were found in the faeces. Eggs were never found in discharges from the fistula though these were often examined. The mucous membrane of the rectum appeared to be normal on rectoscopy.

The Wassermann reaction was negative. Frei test was not possible, but the patient was seen by Favre himself and a diagnosis of lymphogranuloma inguinale was rejected. The author considers the conditions to be a sequel of schistosomiasis, although course of treatment with anthelmintics failed to influence the disease.

Charles W. Wilcock

HALAWANI A. Intensive Treatment of Schistosomiasis with Trivalent Antimony Compounds. *J Egyptian Pub Health Ass* 1948, Nov v 21 No. 9 219-28.

Halawani's paper begins with list of seven antimonials used in the treatment of schistosomiasis, but proves to be a reiteration of two previous papers dealing with the intensive use of Repodral, said to be identical with Fouadim.

These papers were noticed in this *Bulletin*, 1947, v 44, 220 and 329, and the present article does not appear to contain anything new William Alves

DA SILVA, L C T Tratamento da esquistosomíase de Manson pelo stiboplex [Treatment of Schistosomiasis mansoní by Stiboplex] *Rev Brasileira Med* Rio de Janeiro 1947, July, v 4, No 7, 513-17, 3 figs

The drug used, Stiboplex III, is a golden-yellow powder containing 81 per cent metallic antimony and 33.5 per cent iodine. It is soluble in a mixture of equal parts of [unspecified solutions of] sodium tartrate and urethane, and in 1 per cent propylene glycol at 24°C. The same strength in water at this temperature is not quite all dissolved.

The author gives details of experimental work with this compound on artificially infected guinea-pigs, and on its action on the worms *in vitro*. Three mgm of the drug in 1 per cent watery solution daily for 3 days killed the worms in the guinea-pigs, for the *in vitro* tests solutions were prepared varying between 0.7 and 0.0015 per cent of tartar emetic, Repodral and Stiboplex III. Even the highest dilution of tartar emetic immobilized the worms, this result was obtained by the 0.0054 per cent dilution of Repodral and the 0.0109 per cent of Stiboplex, but tartar emetic contains 0.35 gm metallic antimony per gramme, whereas Repodral contains 0.136 and Stiboplex III 0.081 gm per gramme.

Four human cases in which it was tried are detailed, all had undergone splenectomy. It will suffice to record more fully one of the four, for they are all very similar. A lad of 16 years had for some time been feeling weak and incapable of effort and complained of digestive disturbances, diarrhoea with liquid stools containing mucus, more recently a rise of temperature, palpitation, dyspnoea, the liver was enlarged, edge two fingers' breadth below the costal margin, and the spleen was enlarged to the level of the umbilicus, no malaria parasites were found. red corpuscles 3,375,000, leucocytes 4,000 per cmm, eosinophiles 6 per cent, in the faeces were ova of *S. mansoní*, *Ascaris lumbricoides*, *Necator americanus*, *Trichuris trichiura* and *Strongyloides stercoralis*. Splenectomy was performed without mishap, 7 weeks later, he was given an intravenous injection of 2 cc Stiboplex solution, three days later 3 cc, the next two doses of 5 cc at 3 day intervals, after 6 days, he was given 7 cc at 3-, 3 and 4 day intervals, all intravenously. He also had daily injections of 20 cc of 50 per cent glucose and vitamins C and B complex. After the second 7 cc dose, examination of the faeces revealed no ova of *Sch. mansoní* [nothing is said of the other infestations] and the blood showed an eosinophilia of 42 per cent [total leucocytes not stated]. In another patient, subsequent to the treatment, the eosinophiles made up 61 per cent.

The author acknowledges that four cases are too few for any generalization, but says that treatment should be "based on the principle of increasing doses at short intervals of 1 to 3 days at a rate of 10 to 12 endovenous injections, starting with 3 cc of the commercial solution to 7 to 8 cc for adults."

H Harold Scott

JANSEN, G Profilaxia experimental da esquistosomose de Manson [Attempts at Prophylaxis of Schistosomiasis mansoní] *Mem Inst Oswaldo Cruz* 1946, Sept, v 44 No 3 549-78, 20 figs, 1 chart & 1 map

This paper is a sequel to, or amplification of, the author's publication of 1943 [this *Bulletin*, 1945, v 42 1018]. He presents a line map of the Catende district and several photographs depicting the terrain, the construction of model baths, wash-houses and latrines. He examined, once each only, the faeces of 6,559 persons and found ova of *S. mansoní* in 3,482 (53.1 per cent). The faeces were diluted with water, passed through fine gauze, centrifuged and

the deposit examined microscopically. The results are given in age-groups. Of 651 up to 40 years of age 6.6 per cent. were positive of 730 between 5 and 9 years 37.1 of 780 between 10 and 14 years 68.0 of 1 607 between 15 and 24 years 71.7 of 1 158 in the next decade 81.1 after which a steady decline was observed to 35.4 per cent. of 288 over 55 years. The vector is *Anatolobes centratrialis*.

Of the drugs used for treating human cases the most successful was tartar emetic 1,348 were thus treated and 1 159 or 85 per cent. were cured. Maciel's method was adopted 1 per cent. solution injected *in a remora* 0.05 gm. on the first day and, if there was no appreciable reaction 0.1 gm. the next day till 0.95 gm. has been given in 10 injections. If there are signs of intolerance such as diarrhoea, nausea, vomiting and cough the dose is reduced again to 0.05 gm. The next best drug was stibetin intravenously 97 being cured out of 160 (56.8 per cent.) the same drug intramuscularly cured only 42 out of 292 (14.3) antimonyl on the other hand proved better by the intramuscular than by the intravenous route but the number treated intramuscularly was very small only 12, of whom 5 were cured of 117 injected intravenously 39 (31.1) were cured stibin intramuscularly cured 11 out of 50 (22 per cent.)

PAX, C. Studies on Acquired Tolerance to Tartar Emetic, Antimony Sodium Thioglycolate and Neostam. *Chinese Med J Shanghai* 1946 July Aug v 64 Nos. 7/8, 181-201 4 figs. [12 refs.]

An investigation of the various factors which may produce tolerance to antimony was studied in rats and mice tartar emetic, antimony sodium thioglycolate and neostam were used. The decrease in lethal effect of the drug following the administration of one or more initial doses in different percentages of the lethal dose and after various time intervals between the doses was used as a criterion of tolerance. In rats about 50 per cent of the lethal dose given initially was optimal for producing tolerance and in the case of tartar emetic a single initial dose was satisfactory. In other cases, the best method of spacing the doses differed for rats and mice. If the interval between initial doses of the drug was too short a sensitivity to the substance sometimes developed. The mechanism of development of tolerance is discussed. Both tri- and pentavalent antimony compounds were found not to be cumulative in action and each type is equally effective in producing tolerance. The toxicity of tartar emetic was notably increased by starvation of the experimental animals. J D Fulton

LATNER, A. L. COXON R. V. & KING E. J. Measurement of the Concentration of Miracid in Biological Fluids. *Trans. Roy Soc Trop Med & Hyg* 1947 Sept. v 41 No 1 133-40 3 figs.

Miracid (1-diethylaminoethylamino-4-methyl thioxanthone)

was synthesized in Germany and gave promising results in the treatment of experimental schistosomiasis. Methods for its estimation in biological fluids are described in this paper. The fluorimetric method proved unsatisfactory. That of BRONIE & UDEKRECHT (*J Biol Chem* 1945 158, 705) applied by KIRC *et al* [this Bulletin 1948 43 822] to the estimation of paludrine by taking with a dye was tried by the present authors but has not been fully developed.

They finally adapted a simple colorimetric method, in which the yellow colour produced by miracid extracted from 5 ml of blood and dissolved in 0.04 N HCl was read in a Spekker absorptiometer with ultra-violet light and special filter. By this means, 10 to 100 $\mu\text{g}/100\text{ ml}$ could be estimated. After the blood was haemolysed by distilled water, the mixture was made alkaline and then extracted twice with ether, which was in turn washed with alkali and water, and then extracted with HCl of definite concentration before readings were made in the absorptiometer. The amount of miracid present was determined from a calibration curve. Recoveries of miracid added to blood varied from 80 to 110 per cent. Similar results were used for estimating miracid in urine and the error was not greater than 10 per cent.

PESIGAN T P TORRES, L F, Jr & RECIO P M Paragonimiasis Westermani an Unexpected Case with Cystic Formation in the Anterior Abdominal Wall
J Philippine Med Ass 1947 July, v 23, No 7, 293-8 2 figs on 1 pl

WU, K Fasciolopsis in Guinea Pigs with a Summary of the Definitive Hosts
Chinese Med J Shanghai 1946, July-Aug, v 64, Nos 7/8, 219-23, 4 figs on 1 pl

Experimental feeding of *F. buski* cysts to 16 guineapigs gave one positive result, in which immature worms were found in a guineapig which died prematurely. From this and previous investigations it is concluded that these animals are probably not suitable for laboratory work with *F. buski*. Previous work, by the author and other authorities, on the definitive hosts of this worm is summarized in a table.

VON BONSORFF, B Does Feeding of *Diphyllobothrium latum* Influence the Interaction between the Intrinsic and the Extrinsic Factors of Castle? *Diphyllobothrium latum* and Pernicious Anemia VIII
Acta Med Scandinavica 1947, Oct 15, v 129, No 1, 59-76, 8 figs

"The addition of fresh or dried *Diphyllobothrium latum* has not the power to nullify the antianemic effect of mixtures of extrinsic and intrinsic factors when given to patients with cryptogenetic pernicious anemia, the administration of dried worm does not hinder the remission after worm cure in pernicious tapeworm anemia, and the admixture of dried worm to hog's stomach preparations does not diminish their therapeutic effect."

ALLEN, R W The Thermal Death Point of Cysticerci of *Taenia saginata*
Parasitology 1947, Aug, v 33, No 4, 331-8 [11 refs]

"1 A series of experiments was carried out to determine the thermal death point of cysticerci of *Taenia saginata*. After the cysticerci were exposed to various temperatures, attained gradually, they were tested for viability by the use of one or all of the following criteria: (1) ability to evaginate in warm sodium taurocholate solution, (2) activity of flame cells, and (3) the ability to pass through the digestive tract of man without being digested.

"2 Decapsulated cysticerci heated to temperatures as high as 54°C evaginated partially in sodium taurocholate solution and showed active flame cells in some cases. A small percentage of those heated to 55°C evaginated partially in taurocholate solution but none showed active flame cells. Those heated to 56°C did not respond in taurocholate solution, did not show active flame cells, and were completely digested when passed through the digestive tract of a human subject.

3. Cysticerci that were heated in muscle tissue to temperatures as high as 50°C. evaginated in taurocholate solution and showed active flame cells. A small percentage of those heated to 55°C. evaginated partially but none showed active flame cells. However 3 out of 8 were not completely digested when passed through the digestive tract of a human subject. Cysticerci heated gradually in muscle tissue to temperatures of 56°C. and those that were heated to 57°C. did not respond in taurocholate solution, did not show active flame cells, and were digested when passed through the digestive tract of a human subject.

A case in child aged 4.

LARSH, J. E. Jr. The Role of Reduced Food Intake in Alcoholic Debilitation of Mice Infected with *Hymenolepis*. *J. Parasitology* 1947 Aug v 33 No 4 339-44.

A suggestion that malnutrition, brought about by alcoholic debilitation, may have been an important factor in weakening the resistance of young mice to infection with *H. nana* var. *fraterna* as previously demonstrated by the author [this Bulletin, 1946 v 43 759] led to the present studies. Having demonstrated that alcoholic mice consumed much less food per day than non-alcoholic controls, the latter were forced to fast daily during the experiment so that their food intake was about the same as that of the alcoholic mice, and after infection they showed a percentage development of cysticercoids which was about the same as that of the alcoholic mice but considerably higher than that of the non-alcoholic, non-fasting controls. Thus the effect of the alcohol in reducing resistance to *Hymenolepis* infection is indirect and operates by interfering with the normal food intake. Subsequent tests showed that this reduced resistance was mainly due to avitaminosis. J J C Buckley

Report of a case.

BENAIM PINTO, H Aspectos cardio-vasculares de la anquilostomiasis, con especial referencia al problema de la miocarditis crónica [Cardiovascular Disturbances in Ankylostomiasis, with special reference to the Question of Chronic Myocarditis] XII Conferencia Sanitaria Panamericana Cuadernos Amarillos Publicaciones de la Comisión Organizadora No 26 Caracas 1947 452 pp, numerous illustrations [Bibliography]

This exhaustive work was presented as a thesis for the M D degree of the Central University of Venezuela. The question of chronic myocarditis is a serious one in Venezuela, its causes are several and the problem is not purely medical but also economic and social. Circulatory disturbances arise in part from dietetic causes, in part from syphilis, in part from trypanosomiasis (Chagas's disease), in part from schistosomiasis, and in part from ankylostomiasis. The last is dealt with fully in this thesis, the first also comes into play in association with hookworm disease, the other known causes receive mere casual mention.

It is estimated that there are some two million persons in Venezuela harbouring hookworms, more than half the total population, and the concomitant circulatory disturbances are of general clinical importance and of interest to many others than specialists and cardiologists. Some of the associated symptoms have been ascribed hitherto to "hookworm anaemia", but much of the cardiac distress, perhaps to a degree resulting in death, is due to myocarditis.

This volume takes up and discusses minutely various aspects of the problem, mostly with quotations or abstracts from other authors. There are more than 500 references in the bibliography. The author's observed cases numbered 28, their ages ranged between 8 and 70 years, only six were children, 17 were males, 11 females. All the men were agricultural workers, the women did domestic work, occasionally helping in the fields. The degree of anaemia was severe: red cells 960,000 to 2,960,000 per cmm, with an average of 1,759,350, haemoglobin 10-50 per cent, average 29, six were suffering from schistosomiasis and others had syphilis also, only 14 could be considered as suffering from uncomplicated hookworm myocarditis. The commonest symptoms were dyspnoea, praecordial oppression, vertigo, tinnitus and headache, oedema, pulsating jugulars, hydropericardium in one patient, hydrothorax in two [recorded as 3.5 and 7 per cent respectively], anasarca in six, gallop rhythm in eight. The chief pathological change in the heart was a fatty degeneration referable to the anaemia, with cellular infiltration, interfibrillar oedema and increase of connective tissue—all non-specific. Secondary hepatic lesions were naturally present. Each of the 28 cases has a detailed report, with, in most instances, reproductions of the electrocardiograms which are very clear, and X-ray photographs of the thorax, less clear.

LIE KIAN JOE *Trichostrongylus* Infection in Man and Domestic Animals in Java *J Parasitology* 1947 Aug, v 33 No 4 359-62

Post-mortem examinations of 119 Indonesians and 32 Chinese revealed *Trichostrongylus* infections in 49 and 6 respectively. *T. colubriformis* was present in every positive case while *T. axei* was found 11 times, in Indonesians only. The number of worms in one individual is usually very small, but in one instance over 5000 were collected. The duodenum and upper part of the jejunum are the most common habitats.

Experimental infections of a human volunteer were carried out, with larvae of *T. colubriformis* cultured in faeces of a naturally infected goat. These were successful by the oral method, but cutaneous exposure gave negative results.

Similar experiments with *T. axei* were negative. Young goats were easily infected with *T. colubriformis* larvae from human sources both in this and in the human experimental infection 21 days elapsed between exposure and first appearance of eggs in the stools.

No symptoms of sickness accompanied the human infections, but there was a transient eosinophilia to 10 per cent.

FAIN A. Répartition et étude anatomo-clinique des filarioses humaines dans le territoire de Banningville (Congo Belge). (*Wuchereria bancrofti*—Cobbold, *Filaria loa*—Guyot, *Dipetalonema persians*—Manson, *Dipetalonema streptocerca*—Macfie et Carson *Onchocerca volvulus*—Leuckart) [Survey and Anatomical and Clinical Study of Human Filariasis in Banningville (Belgian Congo)] Ann. Soc. Belge de Méd. Trop. 1947 Mar 31 v 27 No 1 25-63 7 figs. [22 refs.]

The observations upon which this paper are based were made in the Banningville Territory (Belgian Congo) which is situated between 16 and 19° long E intersected by 4° lat. S.

The territory is watered by important rivers of which the principal are the Kwango to the east and Kasai to the west. The population is sparse grouped in villages and hamlets of 100-200 persons. Two thousand five hundred Africans were examined, and these comprised about one-tenth of the adult population. Thick blood-films stained by Giemsa were employed.

A focus of *W. bancrofti* of the periodic type producing clinical manifestations described in other endemic regions was studied for the first time in the Belgian Congo along the course of the Kwango river. The endemic area is confined to the course of the larger rivers.

Several specimens of the adult stage of this worm were obtained for the first time in the medical history of the Congo. The females were entwined in association with the males, usually enclosed in cavernous tissue; the males, on the other hand, were often found free and extended, making their way through healthy tissue; thus, several were discovered in the centre of the testis.

Adenopathies and lymphatic varices, and hydroceles were most frequently encountered, and elephantiasis affects about 4 per cent, with predilection for the lower extremities. Filarial lymphangitis was not encountered.

Several small endemic foci of *Onchocerca volvulus* were discovered in Banningville territory. The only clinical signs observed were cysts or nodules almost exclusively confined to the iliac cysts.

There appears to be no relation between the presence of subcutaneous cysts and the presence of *O. volvulus* microfilariae in the skin. About twice as many people harboured microfilariae in the skin as did those who exhibited cysts. On the other hand, cysts containing viable microfilariae may be present and at the same time the latter may be absent from the skin.

Of greater interest is the discovery of *Dipetalonema streptocerca*. This classification is adopted on the authority of PIERI and CHARDONNET (this Bulletin 1947 v 44, 339) who have shown that the parasite of the chimpanzee is almost identical with that of man. The distribution of this filaria is regulated by little-known factors. On the whole it predominates in the south, but it is also found along the course of the Wamba and Kwango rivers. No clinical manifestations were observed in association with this parasite. It may possibly be coincidental that it is closely associated with goitre.

Acanthocheilonema persians is uniformly distributed amongst the native population. The average percentage may be as high as 60. The riverside villages are more heavily infested than those more remote from the larger rivers.

No clinical manifestations were observed

Loa loa is rare in the territory, and the few cases encountered were probably imported. This is probably explained by the absence of the insect vector

P. Manson-Bahr

DILLER, W. F. Notes on Filariasis in Liberia. *J Parasitology* 1947, Aug., v 33, No 4, 363-6

Diurnal and nocturnal blood surveys for filariasis were carried out on Liberian natives. Blood smears taken by day from 2,134 persons gave 14 cases of *Wuchereria bancrofti* and 2 of *Acanthocheilonema*, while those taken at night from 955 showed 8.7 per cent positive for *W. bancrofti* and one case of *A. perstans*. Many cases of elephantiasis were observed, of which scrotal enlargement was the principal type. A blood survey of 431 American soldiers who had been stationed in Liberia for a year or more proved negative for microfilariæ.

Dissections of 649 mosquitoes, mostly *Anopheles gambiae*, gave evidence that this species is the probable vector of *W. bancrofti* in the area

Experimental Chemotherapy of Filariasis. *Trans Roy Soc Trop Med & Hyg* 1947, Sept., v 41, No 1, 18-43, 1 pl & 1 chart [11 refs]. Discussion 44-54, 1 chart [WENYON, C. M. (President), ROGERS, L., NAPIER, L. E., HAWKING, F., FAIRLEY, N. H., MANSON-BAHR, P., GOODWIN, L. G., JOHNSTONE, R. D. C., CULBERTSON, J. T. (in reply)]

CULBERTSON gave an account of the experimental work done by himself and his colleagues on the chemotherapy of *Litomosoides carini* infections in cotton rats (*Sigmodon hispidus*), of *Wuchereria bancrofti* infections in man, of *Loa loa* infections in man, and of *Onchocerca volvulus* infections in man.

In cotton rats, naturally infected with *Litomosoides carini*, it was observed that intensive treatment with pentavalent antimony cures the infection [see this *Bulletin*, 1944, v 41, 772 and 1947, v 44, 229]. The adult worms live in the pleural space of the rat, and microfilariæ occur in the blood. Antimony compounds, such as neostam, neostibosan, and solustibosan, kill the adult parasites in 2 weeks or less, as shown by autopsy, a single massive dose of the drugs often being effective in this; microfilariæ, however, linger in the blood, possibly after a temporary drop in number, for months, but once they vanish they do not reappear. The adult worms are evidently much more vulnerable to treatment than are the microfilariæ. On this important observation is based a re-examination of the drug treatment of the human filariases.

One hundred and twenty-nine Porto Ricans, shown to be infected with *W. bancrofti* but only 3 of whom had clinical evidence of their infections, were variously treated with 4 pentavalent antimony compounds (neostibosan, neostam, urea stibamine and stibanose), with 3 trivalent antimony compounds (fouadin, anthiomaline and tartar emetic), and with an arsenical (melarsen oxide) [see this *Bulletin*, 1946, v 43, 54, 354, and 763]. Microfilarial counts were made on each patient, at a fixed hour, in 60 cmm of nocturnal blood, when these failed to yield microfilariæ, 10 cc of blood were examined by a concentration technique. Fifteen control persons were similarly observed. These latter continued to show microfilariæ throughout the period of observation, but in those cases treated with the drugs, microfilariæ vanished in a considerable number of instances after some months. The results of treatment are summarized in the following table —

| Drug | Number of patients treated | Number of patients freed of microfilariae |
|--------------------------|----------------------------|---|
| Neostibosan | 35 | 25 |
| Neostam | 11 | 5 |
| Urea stibamine | 8 | 4 |
| Stibanoes (Solustibosan) | 5 | 1 |
| Foundin | 15 | 3 |
| Anthracinaline | 20 | 7 |
| Tartar emetic | 4 | 0 |
| Melarsen oxide | 18 | 8 |

The drugs were given in high dosage to produce these results and some of them especially foundin produced severe drug reactions. neostibosan was the most satisfactory and was well tolerated. The blood levels of antimony attained with the various compounds did not bear a constant relationship to the successful eradication of the infection and the destruction of the adult worms did not lead to elephantiasis or other physical signs of filariasis in the patients. The author does not consider that any of the drugs tried so far are ideal agents for therapeutic use and he recommends caution in treatment, lest this prove more hazardous to the patient than the infection.

Three patients suffering from *L. loa* infections all of whom had, or had had Calabar swellings, but only one of whom had microfilariae in the blood, were given an intensive course of neostibosan for two weeks. The two patients with recurring Calabar swellings ceased to suffer from these and the one with microfilariae, but no current swellings, 15 months later had only 8 per cent. of the number present before treatment.

Forty Mexican patients with onchocerciasis nearly all of them with severe ocular manifestations, three being blind, were divided into two equal groups. One of these groups was treated intensively with neostibosan intravenously for two weeks and the other was kept as a control. Several of these patients towards or after the end of the course of treatment became frankly ill as a result of it, and one died 3 days later with evidence of renal damage. None of the controls was ill. The estimation in these patients of the levels of their infection rested on counts of microfilariae in skin snippings taken from each cheek and each side of the neck, irrespective of the site of any nodules which might be present. As a result of the unfortunate fatality it proved difficult to follow the cases adequately however one patient was studied for 5 months, and seven others for 10 months. On comparison with the controls it is difficult to find any evidence of permanent effect of the treatment on the microfilarial levels of *Onchocerca volvulus* in the skin snippings of these patients.

[This paper should be consulted in the original by those interested. It contains detailed information that it is impossible to summarize the dosages of the drugs used, and other relevant data, are set out in numerous tables and charts.]

In the discussion which followed, Rogers recapitulated his pioneer observations on the treatment of *W. bancrofti* infections with sodium antimony tartrate [see this Bulletin 1920 v 15 234 and 1921 v 17 85] and he now thought that CURRIERSON's demonstration of the lengthy survival of microfilariae in the blood after successful treatment confirmed his original belief that he had successfully destroyed the adult worms in his cases. He then discussed the aetiology of the periodical attacks of febrile lymphangitis which are a feature of Bancroftian filariasis. After summarizing the records in the literature on the

drug treatment of this infection, he suggested that ALVES and BLAIR's intensive treatment with trivalent antimony salts [see this *Bulletin*, 1946, v 43, 344] was worthy of investigation in this connexion

NAPIER recorded some experiences in the treatment of filariasis over 25 years in Calcutta. He concluded that a number of cases of filariasis suffering from kala-azar must have been cured of their infections by the antimonials employed in the treatment of the latter disease. He thought the failure to demonstrate the curative action of these drugs in his cases of filariasis was due to the fact that examinations were not pursued for sufficiently long to recognize that cure had been achieved.

HAWKING referred to the treatment of filariasis in E. Africa with various compounds, more particularly foudadin which was pushed to the toxic limit, and considered that the failure to appreciate the effect of these compounds was attributable to ignorance as to the longevity of microfilariae, a subject on which light had now been thrown by CULBERTSON and his colleagues. He remarked on the ease with which *Litomosoides* infections can be maintained in cotton rats in Britain through the vector mite, *Liponyssus bacoti*, and referred to the infectability of ordinary laboratory rats, mice, hamsters and Orkney voles, but he considered these unsuitable for chemotherapeutic work as the infections are light, and tend to die out spontaneously. He made some observations on the activity of various compounds on experimental filarial infections, and stated he had found arsenical compounds even more active than antimonials, and that half-grown immature worms are much more resistant to drugs than fully-grown worms, which might account for some of Culbertson's failures to cure.

HAMILTON FAIRLEY, MANSON-BAHR, GOODWIN, and JOHNSTONE also contributed to the discussion. In reply, CULBERTSON dealt with some of the many points raised and concluded with extracts from Manson's diary, written in 1892-93 suggesting that Manson had demonstrated some therapeutic action of thymol in a case of filariasis carefully observed at intervals for 12 months.

A. R. D. Adams

WHARTON, D. R. A. Pathological Changes in Natural and Experimental Filariasis in the Cotton Rat. *J. Infect. Dis.* 1947, May-June v 80, No 3, 307-18, 15 figs. [18 refs.]

"Pathological changes in the cotton rat *Sigmodon hispidus*, infected with the filarial worm, *Litomosoides carini*, are here described. The only clinical sign associated with the infection is a palpable spleen. The infection gives rise to the formation of papillary nodules that may cover the visceral and parietal pleura. The nodules arise from a proliferative edematous reaction of the pleura followed by infiltration of lymphocytes, neutrophils and eosinophiles, and, later, plasma cells and fibrocytes. Thick laminated fibrosis and enlargement of the lymphatics of the pleura occur in heavy infections.

The lung tissue shows scattered eosinophilia and hypertrophy of the lining alveolar cells. Eosinophilia is characteristic of the pulmonary blood but not of the peripheral blood. The larger bronchioles may be involved in a markedly eosinophilic edematous reaction suggestive of asthma.

Living microfilariae are numerous in the pulmonary vessels but are not centers of reaction. The size of the spleen is two and one-half times that of the normal organ. The spleen shows follicular hyperplasia. *Bartonella* has not been observed. Peritoneal and occasionally inguinal lymph nodes may be enlarged.

The differential white blood cell count appears essentially unchanged.

Adult worms may migrate through the mediastinum or be immobilized and destroyed there.

The pathological effects here recorded have been reproduced experimentally in normal cotton rats. The reaction in the host seems to be due primarily to excretions of the living adult worms and not necessarily to the disintegration of dead worms. Circulating living microfilariae appear to have little if any effect. The reaction is characterized by edema and eosinophilia and is considered to be predominantly allergic.

The significance of these findings in relation to the pathological changes in human filariasis and elephantiasis is discussed."

DEFICIENCY DISEASES

KODICK, E. CARPENTER, K. J. & HARRIS, L. J. "Pellagranic" Astenia of Malice. Further Experiments. *Lancet*. 1947 Oct. 25 816-17 [12 refs.]

In 1946 the authors reported [this *Bulletin* 1947 v 44 119] that growth-rate in rats is retarded by the addition to their diet of indole-3-acetic acid, a substance of which a precursor is present in significant amounts in maize. This effect was counteracted by the addition to the diet of either nicotinic acid or tryptophane.

In subsequent trials, these results have not been consistently reproduced. A number of control animals on the basal diet have shown depression of growth and the proportion of rats on the indole-3-acetic acid diet showing retardation is no longer significantly greater than in the control series. Other workers have experienced similarly irregular results.

Rats given a 40 per cent. maize diet do however show the same retardation curable by nicotinic acid or tryptophane, as was previously observed.

In the search for a possible toxic factor in maize the maize-meal was extracted by a procedure designed to remove the indole-3-acetic acid and which, at the same time removed a protein fraction. Rats fed on the extracted meal showed little or no growth retardation. Feeding experiments with the extract and with fractions derived from it have so far given inconclusive results.

It is suggested that the erratic responses observed by several workers in this field may be due to change in the bacterial flora of the intestines and consequent change in microsynthesis, possibly brought about by the prolonged use of synthetic diets.

The present findings make it seem very unlikely that indole-3-acetic acid can be responsible as such for the apparently more constant pellagranic activity possessed by maize.

Dean A. Smith

PÉREZ, J. C. La pelagra en la República de Bolivia. [Pellagra in Bolivia.] *Hospital* Rio de Janeiro. 1945 Oct. v 28, No. 4 543-57 English summary

A general account of pellagra the origin of its name, the history of the disease, its causation and symptomatology followed by the narration of a case in a man of 35 years in Cochabamba, who is believed to have contracted the disease owing to the low diet resulting from the war between Bolivia and Paraguay. Cure was obtained rapidly from administration of nicotinic acid in tablets of 0.05 gm. taken twice daily before the principal meals, in combination with injections of liver extract (form and dose not stated) which the author thinks is a valuable adjuvant to the nicotinic acid. SPRUE

- 1 FRAZER, A C *Aetiology of Steatorrhoea* *Brit Med J* 1947, Oct 25, 641-5, 3 figs [22 refs]
- 11 BLACK, D A K & FOURMAN, L P R *Some Problems of Tropical Sprue* *Ibid* 645-7 [11 refs]
- 11 BRITISH MED J 1947, Oct 25, 660-61 [13 refs] *Fat Absorption and the Sprue Syndrome*

1 Steatorrhoea is observed in tropical and non-tropical sprue, coeliac disease, pancreatitis, gastro-colic fistula and other conditions. The process of fat absorption may be divided into an intraluminal phase (when it is prepared for absorption), an intracellular phase (in which the fatty material passes through the intestinal cell), and a distribution phase (when the fat is dispersed from the intestine by various pathways into the body).

Intraluminal phase—Fat is digested as triglyceride and there is no doubt that the fat is finely dispersed as an emulsion of particles less than 0.5μ in the lumen of the small intestine.

In normal persons, the contents of the upper two-thirds of the intestine are acid (pH 6.5) and fat is absorbed in triple combination—fatty-acid-bile-salt-monoglyceride.

It may be concluded that long-chain triglycerides are partially hydrolysed in the upper part of the small intestine to fatty acids and lower glycerides, and that these two substances, with bile salts, provide the emulsifying system by which the remaining glycerides are dispersed into fine particles.

These changes normally occur in tropical and in non-tropical sprue and in regional ileitis, but not in conditions which interfere with any of the essential components of the emulsifying system.

Intracellular phase of Fat Absorption—Many water-soluble materials appear to pass through the outer membranes of the intestinal cell. Fatty acids pass into the intestinal cell possibly in the form of soaps.

Severe cases of sprue may show marked disturbance of water and electrolyte metabolism.

It has been suggested that adrenal cortical deficiency may be an aetiological factor in the sprue syndrome, but on the other hand, patients with non-tropical sprue can be relieved of any suggestive signs of adrenal insufficiency by appropriate treatment, without any change in the quantitative aspect of the fat-absorption defect.

Under special experimental circumstances, re-synthesis of triglyceride can be demonstrated *in vivo*. There is little evidence that it is an important feature in normal fat absorption. It seems possible that one important function of phosphorylation in the intestinal cell is to provide phospholipid for the change in interfacial film structure which must occur if the fat particles are to remain in a dispersed state in the protein environment of the bloodstream.

The author discusses the action of choline, and the theory that a defect in phosphorylation may be an aetiological factor in sprue.

Deficiencies of riboflavin or nicotinic acid are frequently associated with fat-absorption defects, especially the sprue syndrome. It is possible to obtain dramatic relief of signs and symptoms of deficiency by administration of the appropriate vitamins, without any measurable change in the fat absorption defect. A riboflavinosis and other vitamin deficiencies occur, in which fat-absorption is normal. It may be concluded that vitamin deficiencies, except, possibly, that of choline, are probably not concerned with the aetiology of fat-absorption in sprue.

Distributive Phase of Fat Absorption—Fat may be absorbed by at least two distinct mechanisms, each of which uses a different distributive pathway. The proportion of fat which is absorbed in particulate form may be reduced, with a corresponding increase in fatty acid absorption. The main factors which seem to be concerned in changes in the distributive phase apart from obstruction in the lymphatic pathway are the pH in the intestinal lumen and the composition of the dietary triglyceride.

ii. Neutral fat is absorbed as a very fine emulsion and when absorbed, enters the lacteals and alternately the systemic blood stream, when it may be visible as fine particles (chylomicrons). Split fat on the other hand, enters the portal system and may be absorbed without increasing the chylomicrons. In practical experience the authors have found the chylomicron count of limited value as a measure of fat absorption in view of the great variation in the size of the particles.

The authors used three methods of studying fat absorption in patients, namely chylomicron counts serum lipid curves and fat-balance experiments. As the result of experience they came to rely mostly on the last method. A significant difference was established between the fasting values in 9 normal persons and 16 patients with sprue in the latter the total fat was only slightly lower than normal after the meal, the increment in total fatty acid in those with sprue was only about half that in the normal persons but the normal range of fat curve was very wide, so that in the individual patient with sprue the curve might fall within the normal range. It was found that variation between successive four-day stool collections was very great, and in order to reduce error all results have been considered in twelve-day periods.

The excretion of fat can introduce only a small systematic error

Normal people taking a mixed diet containing 50 to 100 gm. of fat daily will absorb over 90 per cent. of it but in 28 patients with early tropical sprue fat absorption ranged from 50 to 85 per cent.

In therapeutic trials with nicotinic acid and riboflavin in large doses, no improvement in clinical state or fat-absorption was observed. Large doses of crude liver extract produced rapid clinical improvement but no detectable change in the percentage of fat absorption after several weeks, and thereafter only a slow improvement 15-20 gm. of yeast extract daily however given to patients on liver treatment produced some improvement in fat-absorption in the first 1 days. Folic acid likewise may relieve all symptoms of the disease but does not increase the percentage of fat absorbed. Apart from glucose, the absorption of non-fatty substances in sprue has been little studied. If unabsorbed carbohydrates were as easily recognizable in the stools as are unabsorbed fats, the demonstration of impaired carbohydrate absorption in sprue might not have to be based on the equivocal evidence of blood-sugar curves which are so easily modified by non-absorptive factors. The evidence on this question is mostly indirect. Some general impairment of absorption was suggested by the finding that in the active stages of sprue the dry weight of the stools was increased to a greater extent than could be accounted for by their increased fat content. Iodide and amino-acids were abnormally absorbed. The evidence suggests that there is a fairly general impaired absorption in sprue and that fat malabsorption has been first observed only because its effects on the stools are more obvious.

Salt deficiency—In severe sprue the serum sodium and chloride were both found to be low. It was shown that large amounts of sodium and chloride were lost in the watery stools. Sodium was practically absent from the urine although chloride was still present in half the normal amount. This represents the biochemical pattern of salt deficiency accompanied by some acidosis.

Two findings are of practical therapeutic significance. Yeast extract in large doses exerts a favourable effect on fat-absorption. Secondly, a number of patients become acutely ill with salt deficiency dehydration associated with watery diarrhoea. In such patients, the diarrhoea must be controlled with sulphaguanidine and parenteral liver and the diet supplemented with moderate amounts of salt.

iii The editorial discusses the significance of these two papers and refers to other relevant work. It concludes that, "if our understanding of the physiology of fat absorption is imperfect, enough has been said to show that the absorptive defects in the sprue syndrome are even more mysterious." *P Manson-Bahr*

GELFAND, M. **Sprue and Coeliac Disease in Tropical Africa** *Trans Roy Soc Trop Med & Hyg* 1947, v 41, No 1, 109-18

The author has seen, and reports a case of, coeliac disease presenting the classical picture in an African child of 5, and he also reports a case of this condition in a European child of 2½ years. Both cases were rather milder in type than those encountered in Europe, and both did well under treatment.

It is generally held that tropical sprue is rare, if it occurs at all, in the dark-skinned races. The author has not seen this disease in an adult African. It is also said that sprue is rare in Europeans in Africa. Since 1941, the author has seen three elderly Europeans with incomplete sprue, in Rhodesia. All were originally diagnosed as suffering from malignant disease, in view of the wasting, all recovered on suitable dietary treatment.

Kwashiorkor (infantile pellagra) occurs in young children (1½ to 4 years) throughout most of tropical and subtropical Africa. The author considers the condition *not* primarily dietetic in origin for the following reasons—The onset is abrupt, in an apparently healthy child, the mother and other children in the family are usually well, the diets of the affected children appear to be adequate and kwashiorkor would not be so fatal if it were of nutritional origin, especially when it is diagnosed early and treated with an adequate diet. Suspecting that kwashiorkor might be due to jejunal deficiency, the author performed fat analyses on some cases, in some there was steatorrhoea, in others none, the results therefore do not support this thesis, or that kwashiorkor is a sprue-like disease. The author's belief is that it is primarily a liver disorder and at 3 autopsies he has observed a yellow fatty liver in each case. [Full data are given of examples of each type of case the author discusses.]

HAEMATOLOGY

COURDURIER, J & BRYGOO, E. Considerations sur la vitesse de sedimentation des hematies chez les Noirs en Afrique. [The Blood Sedimentation Rate in Africans] *Méd Trop* Marseilles 1947, May-June, v 7, No 3, 254-9 [16 refs]

In the Hygiene Institute at Douala the authors studied the blood sedimentation rate in 50 healthy ex-service Africans from different parts of the Cameroons. Westergren's technique was used and tests were made each day

at the same time and under identical conditions. Readings were recorded after one and two hours. The average readings were 38.2 and 57.3 respectively but the variations were so great (0 to 137 for the first hour, 2 to 145 for the second) that these averages are of little value.

The authors discuss the various factors which might account for these high rates. While they were unable to disprove entirely any meteorological or racial influences, they do not consider that these were significant. Many parasitic infestations were found and these are discussed. The authors believe that these must be taken into account in assessing what constitutes a "normal" African—those in apparently good health, living with their parasites and living active lives would constitute normal people. The authors believe that the anomalies in the B.S.R., including the wide range of figures which made the establishment of an "average" reading impracticable, can be accounted for entirely by the high degree of parasitism encountered in apparently healthy Africans.

In the circumstances, the B.S.R., which is regarded as having a real value in Europe, cannot be considered of much assistance in French Equatorial Africa.

VAN UFFORD, W. J. Q. Over de Bloedbezinkingssnelheid in de tropen. [Blood Sedimentation Rate in the Tropics.] *Ned. Maandblad*. Batavia, 1947 July No. 12, 220-22.

VENOMS AND ANTIVENENES

CHRISTENSEN, P. A. & DE WAAL, Mara. Magnesium Sulphate and Carbolic Soap as Antidotes in Snake-Bite. *South African Med. J.* 1947 Sept. 27 v. 21 No. 18, 680-81.

The good reports on the use of injections of magnesium sulphate solutions by SHIRCORE [this *Bulletin* 1947 v. 44 1017 and see also 1927 v. 24 800 and 1943 v. 40 625] and of 5 per cent. carbolic soap solution by AMUJA and BROOKS [ibid. 1946 v. 43 478] called for confirmation and both have been tested by the present authors in a properly controlled series of experiments. In the first, Shircore's method was followed closely. Dried venom of *Bitis arietans* was reconstituted in saline and 0.2 cc. (equivalent to 4-5 m.l.d. for guinea-pigs) was injected into the hind-leg muscles of each of 16 guinea-pigs and 5-10 minutes later 8 were infiltrated with local injections of 10 per cent. magnesium sulphate solution, the other 8 serving as controls. All 16 were dead within 3½ hours. The magnesium sulphate clearly was valueless against puff adder venom. Next, the protective value of the $MgSO_4$ solution and of the soap were tested against the venoms of *Naja ferox* (the Cape Cobra), *Sepeiden kammachates* (the ringhals) and *Bitis arietans* (the Puff Adder). The m.l.d. (0.06 mgm.) of the cobra venom was injected as before and 5 minutes later 9 guinea-pigs received 1 cc. of the sulphate solution, 9 the same amount of soap solution, 9 received 0.25 cc. antivenene and 9 were left as controls. With the *Sepeiden* venom the same method was used, but 0.5 ml. of antivenene. The *Bitis* venom was injected subcutaneously into the flank instead of intramuscularly because of the damage effected by the latter route, and 2 cc. of antivenene were injected. In a third test, the cobra venom was re-tested, with the use of 0.2 mgm. (or about 3 m.l.d.) and 40 animals were injected, 10 for each method of treatment and 10 untreated controls. The results are

presented in a detailed table, but they may be stated briefly thus the $MgSO_4$ proved valueless, the carbolic soap solution was definitely protective against the cobra and the ringhals, useless against the puff-adder venom, it is to be recommended, therefore, as a first-aid treatment for cobra bites

DE MAGALHÃES, O O combate ao escorpionismo [Against Scorpions] Mem. Inst Oswaldo Cruz 1946, Sept, v 44, No 3, 425-39 [21 refs]

The question of dealing with scorpions is a serious one in parts of Brazil. Scorpion sting may be fatal even to adults, but even when it is not fatal it causes much pain, suffering and distress. In Belo Horizonte, 1,221 cases were recorded in 1941 and in three years 2,529, and, of course, many patients did not consult a medical man and so were not recorded. *Tityus serrulatus* seems to be the commonest and *T. bahiensis* next, but there are also two species of *Parabuthus*, *P. transvaalicus* and *P. triradulatus*, two of *Opisthophthalmus*, *O. wahlbergi* and *O. glabrifrons*, and *Hadogenes trogloditis dentatus*.

DDT, or Neocid in powder, is effectual in killing the scorpion after an interval, for treatment of stings, the appropriate serum given early is the best

MACCHIARELLO, A Cutaneous Arachnoidism or Gangrenous Spot of Chile. Puerto Rico J Pub Health & Trop Med 1947, June, v 22, No 4, 425-66, 5 figs [Refs in footnotes] [Spanish version 467-505]

The author presents a picture of the *mancha gangrenosa*, or gangrenous spot, of Chile. It results from the injection of a necrotizing poison by a spider, *Lorosceles laeta*. Clinically, arachnoidism in Chile may be divided into three groups: (1) Cutaneous, (2) viscerocutaneous, (3) nervous, the last due to the Black Widow spider, *Latrodectus mactans*.

Cutaneous arachnoidism is more common in the northern zone of Chile, from Antofagasta to Copiapó and Ovalle, rare, but not unknown, in the central area, cases are more often seen in the spring and summer, October-April, and more particularly January-April, but in some years no cases are seen. *Lorosceles laeta* is a house-spider, so most cases are "domestic accidents".

The symptoms of cutaneous arachnoidism, gangrenous spot, are nearly always purely local—sharp pain becoming a burning sensation, there are local oedema and erythema which spread, then the swelling hardens, darkens to violet or black by the third day, necrosis of the underlying tissue occurs (sometimes with a covering blister) and sloughing of a large surface up to 30 cm or even more in 2-3 weeks. There may be keloid development later. Strange as it may seem, apart from the first day's pain and insomnia, which are not relieved by morphia, there are no constitutional symptoms. Details of 25 cases illustrating the above are given.

In the viscerocutaneous form, the same spider is the cause and the reason for the production of generalized symptoms (such cases are few) is thought to be the injection of the poison directly into some vessel of the skin. In these patients there are rise of temperature, haematuria, jaundice, asthenia and vomiting. Red corpuscles are reduced by some 60 per cent whereas the leucocytes are increased to about the same degree. Differentially, the chief change is an increase in large monocytes at the expense of the polymorphonuclears.

Study of the poison shows that it is not of itself haemolytic and the pathogenesis of the haematuria awaits explanation. The difference from the bites

of *Latrodectus mactans* rests in the absence of general symptoms and the localized coagulant and necrotic action, whereas *L. mactans* has a special action on the nervous system and the symptoms are generalized. H. Harold Scott

DERMATOLOGY AND FUNGUS DISEASES

DORMER, B. A. & SCHER, P. Case Report X. Tumor of the Lung due to *Cryptococcus histolyticus*. Clin. Proc. Cape Town. 1947 Aug v 8, No. 8, 266-73 6 figs.

NEGROMI, P. FERNÁNDEZ L. L. & DAGLIO C. A. N. A propósito de un caso de pie de Madura con granos negros. Revisión de los micetomas producidos por "Madurella" [Concerning a Case of Madura Foot with Black Grains. Review of the Mycetomas caused by *Madurella*.] *Rev. Argentina Dermatología*. 1947 June v 31 No. 2 192-205 3 figs. [34 refs.] English summary (8 lines)

The authors present a review of the history and nomenclature of the species of the genus *Madurella* Laveran and supplement this with an analytical table of the reported characters of the fungi. They also describe the fungus from a case of black grain mycetoma from Argentina, which they have identified as *Madurella ramiroi* da Silva. A fungus from the same lesion had previously been diagnosed as *Aspergillus chevaleri* by two other pathologists.

[The time is ripe for a revision of the species of *Madurella* some of which are based on a study which did not include the examination of the fungus in saprophytic culture and there is little doubt that several of the specific names should be treated as synonyms of *Madurella mycetomatis*] J. T. Duncan

DE ALMEIDA, F. RIBEIRO D. O. ASHCAR, H., LACAZ, C. da S. & SAMPAIO, S. de A. P. I. Ação da penicilina, in vitro sobre o paracoccidioides brasiliensis. II. Resultados obtidos com a administração desse antibiótico no tratamento da blastomycose sul-americana. I. Ação de Penicillin on Cultures of *Paracoccidioides brasiliensis*. II. Results of Administration of Penicillin to Patients suffering from South-American Blastomycosis.] *Hospital*. Rio de Janeiro. 1946, Jan., v 29 No. 1 181-4 1 fig

I. Reports on the action of penicillin on mycotic fungi have been discordant the studies of KREWY AJELLO and LANKFORD (*Bull. Johns Hopkins Hosp* 1944 v 75 410) led them to conclude that The use of penicillin in the treatment of the superficial and the deep mycotic infections is unwarranted and contra indicated. The present authors, nevertheless, tested its effect on cultures of *Paracoccidioides brasiliensis*. In each of four tubes of Sabouraud broth, pH 8-4 they placed a fragment of the culture obtained on solid Sabouraud glucose. The tubes were then incubated at temperatures ranging from 24 to 48°C. and when growth appeared, there were added daily the first three tubes 1 10 and 50 Oxford units of penicillin respectively the fourth being left as control. Five days later examination revealed that in tube 1 there were more than 32 units, in tube 2 more than 32 and in tube 3 more than 100 units. In spite of continuing the daily addition of penicillin, at the end of ten days the growth in all the tubes was the same. Photographs of the tubes are reproduced in the article.

II. Penicillin was given to each of three patients suffering from different forms of South American blastomycosis. The first with the glandular form,

was given 20,000 Oxford units of sodium penicillin intramuscularly every 3 hours. After a total of 600,000 units had been given, treatment had to be suspended because the patient seemed to be "physically worse". The second, with the cutaneous and glandular form, was given 25,000 units every 3 hours intramuscularly, to a total of 1,300,000 units. The third, with the mucous membrane form, was given 50,000 units in the same way to a total of 3,000,000 units. In all three there was observed at first a slight improvement in the cutaneous and mucous lesions, they were softer and less oedematous, but no further amelioration took place. The early improvement is ascribed to the effect of the penicillin on the secondary infections. In short, in the doses given, the penicillin was without action on the blastomycotic condition.

CAMPOURCY, A. Chromoblastomycose au Cameroun [Chromoblastomycosis in the Cameroons] *Bull Soc Path Exot* 1947, v 40, Nos 7/8 252-3, 1 fig

HABIBI, M. *Rhinosporidium seeberi* en Iran [*Rhinosporidium seeberi* in Iran] *Ann Parasit Humaine et Comparée* 1947, v 22, Nos 1/2, 84-8, 4 figs

Rhinosporidiosis, caused by *Rhinosporidium seeberi*, is a relatively rare mycosis, the total number of reported cases, from all countries, does not exceed 165. Habibi has observed 31 cases in Persia since 1937, before that date the disease had not been recognized in the country.

An analysis of the age incidence in 28 of the Persian cases shows that 10 contracted the infection between the 10th and 20th years, 7 between the 20th and 30th years and 4, 3, 2 and 1 in each of the succeeding decades. Only one patient was under 10 years of age. The disease is not associated with any particular occupation, but the highest number of cases occurred amongst scholars, which may be related to their ages or to the greater possibility of transmission of the infection during play. Geographically, 16 of the cases were connected with Ardebile, 13 with Teheran and 1 each with Ispahan and Kermansha. In 22 cases the polyp arose from the nasal mucosa, in 7 from the conjunctiva of the eye or eyelid and in 2 from both nose and eye. In treatment, strangulation of the polyp at its pedicle with a silk ligature, as practised in the Ardebile district, gives only transient relief followed by recurrence, instillation of a weak solution of tartar emetic, advocated by WRIGHT, proved ineffective, but electro-coagulation of the polyp and its immediate neighbourhood, or surgical excision followed by cauterization of the base of the tumour, gave the most satisfactory results.

LANGERON, M. *Tritirachium brumpti* (Langeron et Lichaa 1934) Langeron 1947 et le genre *Tritirachium* Lumber 1940 [*Tritirachium brumpti* and the Genus *Tritirachium*.] *Ann Parasit Humaine et Comparée* 1947, v 22, Nos 1/2, 94-9, 1 pl & 1 fig [13 refs]

The fungus described from a case of ocular mycosis in Egypt as *Beauveria brumpti* [thus *Bulletin*, 1935, v 32, 898] is here re-named *Tritirachium brumpti* and four other fungi found associated with disease in man are also transferred to the latter genus. The pathogenicity of these five species of *Tritirachium*, which are, in the author's opinion normally saprophytes of world-wide distribution appears to be weak.

HEAT STROKE AND ALLIED CONDITIONS

CONSOLAZIO, W. V., PECORA, L. J. & TURNING, T. A Slow Dissolving, Non-Irritating Salt Tablet for Use in Hot Environments. *J. Indust. Hyg. & Toxicol.* 1947 Sept., v 29 No. 5 347-50 2 figs.

Severe symptoms of nausea, vomiting and epigastric discomfort are frequent as a result of the use of ordinary salt tablets to combat the effects of heat and excessive sweating. It was believed at first that these symptoms were due to prolonged contact of the salt with the gastro-intestinal mucosa. Salt tablets prepared with cornstarch to bring about rapid solution were, however, not satisfactory. Slowly dissolving tablets were then prepared on the assumption that with these the salt concentration might never be great enough to cause irritation of the mucosa. These tablets were found to be very satisfactory in a number of trials.

These slowly dissolving tablets are prepared by treating ordinary salt tablets with a solution of cellulose nitrate or acetate and then drying at 100°C. to remove the solvent. This procedure gives rise to the formation of a honeycomb structure. The impregnating film of cellulose weighs about 4 mgm. per tablet of 0.65 gm. In a few experiments no evidence was found of any toxic effects in animals through the ingestion of cellulose nitrate or acetate. The solution time of the impregnated tablet is of the order of eighty minutes compared with fifteen minutes for the pure salt tablet and one minute for the salt-cornstarch tablet.

M. E. Delafield

TROPICAL ULCER

LICHTMAN, J. A. Tropical Ulcer with special reference to its Etiology. *Chir. Proc. Cape Town.* 1947 July v 6, No. 5 165-86, 14 figs. & 3 charts. [72 refs.]

This paper is based on the personal study of 160 patients treated in Durban, Natal.

It is usually agreed that tropical ulcer may start as —

- (a) infection of a wound or other lesion (most commonly)
- (b) spontaneously as a vesicle which bursts in a few days (probably uncommon.)

Site.—The author in his series found that 41.4 per cent. of ulcers occurred on the anterior surface of the leg in its middle or lower thirds and rarely occurred elsewhere than on the lower extremities (all observers are probably agreed on this). An adherent yellowish-grey slough at the base of the ulcer was a characteristic feature and pain was a frequent symptom. The chief complication was extension especially in depth and in 34 per cent. of cases the ulcer had extended to tendon and bone. Spontaneous fracture of underlying bone has been recorded.]

Surrounding multiple ulcers indicative of auto-inoculation were not uncommon, but lymph-spread was not a feature and no cases of malignant change were found in this series (VINT in Kenya found microscopic malignant changes in 2 per cent. of cases examined). Scars of previous ulcers were found in 43 per cent. which does not support the theory that one ulcer confers immunity.

Bacteriology.—Fusiform bacilli were found in 70 per cent. spirochaetes in 60 per cent. but these were always found together with fusiform bacilli. In only 36.8 per cent. were fusiform bacilli and spirochaetes found without other

Miscellaneous Diseases

Vol 45 No 17

organisms Although other organisms such as Gram-positive diplococci, staphylococci and streptococci were met frequently, the predominating ones were fusiform bacilli and spirochaetes

Diphtheria and diphtheroids were uniformly absent, streptococci were not conspicuous, Leishman-Donovan bodies were not found, either in smears or sections, blastomycosis, actinomycosis, and evidence of other mycotic organisms were not found

The fusiform bacilli and spirochaetes were morphologically identical with those of Vincent's angina, and the author considers that they are causal and pathogenic for the following reasons —

- 1 In 36.6 per cent they were the only organisms found in active lesions,
- 2 They are associated with a definite clinical type and can invade living tissue,
- 3 Tropical ulcer has been reproduced in human beings with pure cultures of fusiform bacilli by intradermal injection plus some form of trauma [see this *Bulletin*, 1946, v 43, 378]

Trauma undoubtedly plays a large part in causation, and contact with saliva (in which fusiform bacilli are often present) is a likely mode of infection. Cases are very rare outside the latitudes 35°N and 10°S, although the author's series come from Durban, 30°S. Local predisposing causes are probably increased liability to injury due to scanty clothing [cf prickly heat] and increased skin moisture predisposing to bacterial growth [cf prickly heat]

Climate — Cases are very rare outside the latitudes 35°N and 10°S, although the author's series come from Durban, 30°S. Local predisposing causes are probably increased liability to injury due to scanty clothing [cf prickly heat] and increased skin moisture predisposing to bacterial growth [cf prickly heat]

The author was unable to incriminate syphilis, malaria, hookworm, bilharzia or anaemia as important predisposing causes, although he does consider that in West Africa sickle cell anaemia may play a part

Dietary deficiency is undoubtedly a predisposing factor. Thus meat- and fish-eating tribes are much more rarely affected than those whose diet is mainly vegetarian and where the protein is of low biological value [cf the rarity of this condition amongst the Masai, who live mainly on meat, milk, and blood, despite the fact that they live under very dirty conditions and are very prone to injuries of the lower extremities]. The author was unable to find evidence of deficient protein content in the serum of ten consecutive unselected cases but he does consider vitamin deficiency, especially lack of nicotinic acid or offlavin, to be an important predisposing cause, he notes the prevalence of "crazy pavement" skin and pigmentation of the legs

Local predisposing causes — Dirt and exposure to injury are regarded as important, but the presence of peripheral neuritis was not noted. The paper contains several tables and some excellent photographs

MISCELLANEOUS DISEASES

CHODZKO, W. Persistent Endemic Foci of certain Acute Infectious Conditions Remarks on their Extinction. *Bull. Office Internat. d'Hyg. Publique* 1946, Oct-Nov-Dec, v 38, Nos 10-11-12, 913-34 [40 refs] [French version 889-912, 3 maps]

The Polish delegate's report to the Permanent Committee ranges over many diseases and presents many facts and ideas of interest. It is worth remembering that Ferran was early in the field, possibly the first in the field with vaccination against cholera in Spain and his vaccine was, like the fixed antirabic virus of Pasteur, a vaccine of living organisms. Mention is made by Chodzko of Rogers' denial that cholera spreads throughout India from Bengal. [One wonders whether an endemic home for cholera, usually allotted to India]

and China, might not be found in the valley of the Russian Don?] Influenza is given its original endemic centre in China, especially in the basin of the Yellow River of North China. An interesting point is made of a frequent association, which manifested itself in Poland after the first world war — epidemic relapsing fever nearly always follows epidemic typhus fever. The phenomenon, which is probably not accidental although the former is a spirochaetosis and the latter a rickettsiosis, also occurred in Algeria, Egypt and Roumania following the first and second world wars. Whenever there is a big world-wide conflagration, the hideous face of louse-borne typhus fever appears on the scene. References are made to the tick-borne and mite-borne typhus fevers and to the great danger of aeroplane introduction of the disease to the prophylactic vaccines that are now available of which the first in order of discovery was the Polish vaccine of Weigl to DDT insecticide and to the Soviet antiseptic soap. Plague although said to have its original endemic centre in central Asia has, at various times swept over Europe. Sylvatic epizootic plague has, perhaps, received more attention of recent years than epidemic plague. The possibility that plague-infected fleas may travel even by ship hidden in bales of fute to start the disease in a distant country is mentioned this subject has received recent attention. Smallpox, like those diseases already mentioned receives a special heading and special commentary. In Russia, vaccination against smallpox started to be carried out in 1803 but it was not until 1909 that vaccinations and revaccinations were made compulsory by a special law which was followed by striking success. Poland freed itself from smallpox in 1919 and since 1836 not a single case of smallpox has been notified.

There is again a special commentary on giardiasis as presenting a special pandemic problem. The author reminds us that the causal agent of the disease, originally known as *Lamblia* owes its name to Professor Lambl, a Czech scientist, and professor of medicine at Warsaw University. The professor himself called the parasite *Cercomonas*. As there are large numbers of carriers of the organism it would appear necessary to introduce compulsory notification of cases of giardiasis which is a real invisible pandemic disease.

B. F. Harvey

ASH, J. E. The Lymph Node in Tropical Diseases. *Amer J Trop Med* 1947 July v 27 No. 4 483-91 10 figs.

In lymphopathia venereum (climatic or tropical bubo) the stellate abscess cannot be differentiated from the granuloma of several other infections, particularly tularemia. It is closely simulated in filarial infection, but is readily distinguishable from that of tuberculosis and syphilis by the type of necrosis.

In scrub typhus, there is generalized adenitis and the glands may show areas of gross necrosis. In Oroya fever the lymph nodes are specifically concerned, because of the involvement of the reticulo-endothelial system. A less specific feature is sinus catarrh. The sinuses are dilated, the endothelium swollen and the lumina filled with lymphocytes and large macrophages.

In yaws, the treponemata are demonstrable, in the lymph nodes.

The reaction of the lymphatic tissue to *Brucella* bears a considerable similarity to that of Hodgkin's disease. Most pathologists have recognized in brucellosis a non-specific and non-neoplastic reaction—such as is seen after irradiation, and which was observed especially in the tissues of Japanese atomic-bomb victims. In *Brucella* infections, especially of *Br. melitensis* origin, it is seen more particularly in the mesenteric glands and spleen, and includes the presence of multinucleated cells indistinguishable from the Reed-Sternberg cell of Hodgkin's disease.

Typhoid fever is a lymphadenotropic infection with a reaction that is usually characteristic enough to warrant identification in absence of other criteria. The typhoid cell is a large mononuclear cell which tends to collect in foci and displace the normal lymphatic tissue.

In all cases of plague, there is localization of *Pasteurella* in the lymph nodes. The primary localization of the organism is there. The toxin of *P. pestis* causes necrosis of the vessel walls, and the reaction is characterized by extensive necrosis and haemorrhage.

In leprosy, involvement of the lymph nodes is a constant feature, so that diagnosis may be made bacteriologically by aspiration of the inguinal glands. In the early stages, pigmented foam cells are scattered near the cortex and contain bacilli. Histoplasmosis is the only fungous disease with a predilection for the reticulo-endothelial system.

In leishmaniasis the lymph node is not particularly involved, except in heavy infections. The glandular lesions of filariasis (*W. bancrofti*) infections are too well known to need further description. *W. malayi* may localize about the mammary gland or in the axilla. An interesting feature of the histology is that eosinophils may be present in lymph nodes in which these worms may not necessarily be identified. *P. Manson-Bahr*

SCHWETZ, J. Sur la rivière Fwa (Congo belge) Notes géographiques, zoologiques et médicales [Geographical, Zoological and Medical Notes on the River Fwa, Belgian Congo] Inst Roy Coloniale Belge—Bull des Seances 1947, v 18, No 1, 271-95, 1 text fig, 5 figs on 2 pls & 1 folding map

"Lake Fwa" in the Belgian Congo is 155 km from Lusambo and 135 km from Luluabourg. Its natural beauty attracted many tourists and a small hotel was built on its banks. Soon after a large proportion of visitors were infected with schistosomiasis. A large number of lakeside native dwellers were likewise found to be infected. The hotel was closed, European visitors ceased to visit the lake, fishing was prohibited, and the villages were removed to a distance from the banks. The author of this report spent twelve days at Fwa and gives the results of his observations.

"Lake Fwa" is not a lake, but a river of an unusual kind. Gushing springs emit such large quantities of water that the resulting river is very many metres wide near its source. The river flows 15 km to join the river Lubi, its width varies from 50 to 200 metres or more.

The author writes enthusiastically of the natural beauties the fish and birds. Mosquitoes were very abundant. Of 722 specimens identified there were 601 *A. funestus*, 99 *A. marshalli* var *moucheti* and 22 *A. gambiae*. Larvae of three other anophelines were found, *A. costanti*, *A. paludis* and *A. obscurus*. *Phlebotomus* and *Culicoides* were very abundant, *P. africanus*, *P. schwetzi*, *P. decipiens* and *Culicoides mornati* pennis. *Glossina palpalis* was found, but was not abundant along the river banks.

The molluscan fauna was rich. 11 species were found. 10 Gasteropods and 1 *Lamellibranch*. There were two species of *Planorbis*. *Biomphalaria adovensis* and *Hydrobia orbis salinarum*.

An examination of 70 villagers in one nearby village revealed 21 with schistosomiasis, 45 with ankylostomiasis and 28 with ascariasis. *Norman White*

DE ALBUQUERQUE, A. F. R. & MACHADO, A. C. Contribuição ao conhecimento da nosologia de Alagoas [Disease in Alagoas] Rev Hig e Saude Publica 1947, Apr-June, v 5 No 1 21-34 2 maps

Alagoas occupies an area of 28 571 kilometres between 8°55' and 10°28' south latitude and 5°15' and 5°10' east longitude of the meridian of Rio de Janeiro

After a brief account of its physiogeography, the authors consider three diseases and their vectors, viz., the Triatomidae, yaws and schistosomiasis.

Of 2,338 Triatomidae examined, 2,328 (99.5 per cent.) were *Paratrypanozoa* and 410 (17.6 per cent.) were infected with *T. cruzi*. 7 were *Extriatoma maculata*, one infected and 5 were *T. brasiliensis* 2 infected. A table gives the distribution of *P. maculatus* in 23 localities—most, in actual numbers and in percentage, were in the wooded districts.

Yaws was systematically taken in hand in 1943 treatment units being established. In 17 of the 33 municipalities the numbers recorded for the three years 1943-45 were, respectively, 1,883 3,523 and 4,625—the numbers in the different municipalities are shown in a table [but this would be of local interest only].

Schistosomiasis mansoni is common in the wooded and maritime regions—the snail hosts are *Australorbis centumtralis* and *A. obsoletus*. Another mollusc, of the genus *Ampullaria*, abounds in the State—one of these was found parasitized by a locked cercaria in 1943. Ten localities are detailed in a table. In Macisé of 15,096 persons examined, 883 (5.8 per cent.) were positive—among 2,646 children in schools in the same district 59 (2.2) were positive—among 2,341 in the Rio Largo district 738 (31.5) were infected. In other places the percentages positive were high—but the numbers examined were small.

GALLO P. & VOGELBEIN E. G. Les zoonoses en Venezuela. [Diseases of Animals in Venezuela.] VII Conferencia Sanitaria Panamericana. Cuadernos Amarillos. Publicaciones de la Comisión Organizadora. No 27. Caracas. 1946, 53 pp. [Bibliography.]

An interesting article, not confined to veterinary diseases, as the title would imply—but a consideration of the diseases common to animals and man, or communicable from animals to man. All the usual diseases are mentioned—rabies, encephalo-mylitis anthrax parasitic infestations, etc. One section of particular interest is that dealing with animals which act as reservoirs of human disease in Venezuela, as howler monkeys and yellow fever rats and plague, canine and human leishmaniasis, opossums and armadillos and Chagas's disease, dogs and *Desmoders* and human rabies.

DEMAN K. Jean-Marie. Un myriapode chulopode *Orphnus brasiliensis nigropictus* Att. de l'oreille humaine en Equateur. [A Myriapod, *Orphnus brasiliensis nigropictus* Att. from the Human Ear in Ecuador.] Ann. Parasit. Humaine et Comparée 1947 v. 22, No. 1/2, 65-7 6 figs.

PROTOZOOLOGY GENERAL

WENRICH, D. H. The Species of *Trichomonas* in Man. J. Parasitology 1947 June, v. 33 No. 3 177-83, 3 figs. [Numerous refs.]

The author returns to the subject of the species of *Trichomonas* in man which he previously discussed (this Bulletin 1944 v. 41 697). He gives further details for their differentiation and discusses the relevant literature. He concludes that the oral form (*T. tenax*) and the vaginal form (*T. vaginalis*) with four anterior flagella are closely related, while the intestinal form (*T. hominis*) possesses five anterior flagella, four of which arise from a single blepharoplast as do the four flagella of *T. tenax* and *T. vaginalis* while the fifth originates in a single small ventral blepharoplast. The author is careful to note that *T. hominis* is the only intestinal form he has seen, but admits that forms with three and four flagella may occur. The paper is illustrated by three diagrams showing the structure of the three species discussed.

C. M. Henry

KIRBY, H. Flagellate and Host Relationships of *Trichomonad* Flagellates *J Parasitology* 1947, June, v 33, No 3, 214-28 [40 refs]

The author discusses the flagellates of the genus *Trichomonas* and other flagellates that have basic features of structure and a type of cell division comparable to that of *Trichomonas*. Many of the forms considered are parasites of termites. C. M. Wenyon

CROSS, JOY B. A Cytologic Study of *Toxoplasma* with special reference to its Effects on the Host's Cell *J Infect Dis* 1947, May-June, v 80, No 3, 278-96, 52 figs on 4 pls [Numerous refs]

The author has studied the morphology of toxoplasma as exhibited by two strains maintained in mice. Material from the peritoneum was used and fixation was always by the wet method—Bouin's solution, Flemming's fluid, Schaudinn's fluid, and 10 per cent formalin. For staining, various methods were adopted, including Feulgen reaction. It is pointed out that in the peritoneal cavity the parasites are both extra- and intra-cellular and when in the latter situation, in spite of their multiplication, they do not interfere with the nuclear division of the host cell. The parasite contains a shadowy band of cytoplasm which divides it longitudinally. This is termed the "cytostyle". Another structure which is occasionally seen is a phlange which stretches from one end of the parasite to the other. It is assumed that the appearance of the parasite as a crescent in dried films is due to the failure of this phlange to stain. Apart from the nucleus a number of granules are present in the cytoplasm. The nucleus is described as dividing by mitosis with persistence of the nuclear membrane. This is specially clear in specimens stained by Feulgen's method. Reproduction is by binary fission, there being no evidence of any schizogonic process. Eventually the intra-cellular parasites are so numerous that the host cell nucleus is extruded, leaving a terminal colony of parasites surrounded by a membrane representing the remains of the host cell. From her observations, the author concludes that the parasite is a protozoon. In three slides, some 50 flagellated organisms were encountered but the author is uncertain as to their identity. The paper is illustrated by a number of drawings.

[It is perhaps unfortunate that no mention is made of the living organisms as these might have served as controls of the fixed specimens, many of which appear to the reviewer to be abnormalities. In fixed specimens, the prevailing type of nucleus is that of a vesicle with small central karyosome.]

C. M. Wenyon

ENTOMOLOGY AND INSECTICIDES GENERAL

HILL, Marjorie A. The Life-Cycle and Habits of *Culicoides impunctatus* Goetghebuer and *Culicoides obsoletus* Meigen, together with some Observations on the Life-Cycle of *Culicoides odibilis* Austen, *Culicoides pallidicornis* Kieffer, *Culicoides cubitalis* Edwards and *Culicoides chiopterus* Meigen. *Ann Trop Med & Parasit* 1947, May, v 41, No 1, 55-115, 12 text figs, 5 figs on 2 pls, 6 graphs & 2 histograms [75 refs]

The primary object of these investigations was to fill in the gaps in our knowledge of the life cycle of *Culicoides impunctatus* and *C. obsoletus*, the most wide-spread and annoying "midges" in Britain.

The paper contains detailed records of twelve months' work in the neighbourhood of Liverpool during 1945-46. It includes a very full survey of the literature on the genus, dealing with the life-cycle, the morphology, British species and laboratory technique.

After describing the site of the investigations, the type of soil, the flora in different plots of ground and the methods and materials employed, the author discusses the experiments made and the conclusions drawn from them. An illustrated account is given of the morphology of all stages of the different species. Data from the experiments are presented in full.

For the collection of adults, netting, light traps and human belts were first employed but were later abandoned. Daily collections were made in the summer of 1945 before sunset each evening as the insects alighted on a black cloth suspended above the ground. Adults were bred in the laboratory in lamp chimneys and feeding was first done on the sorter's arm but later on the shaved ear of a rabbit. Rearing was done in earthenware pots covered with lamp chimneys having organdie fastened over their narrow ends. The medium for *C. impunctatus* was peaty soil and for *C. obsoletus* decaying leaves and mud. Some were kept at 22° to 24°C. but the majority were reared at laboratory temperatures of 16° to 19°C.

From the results of the field and laboratory experiments it was concluded that *C. impunctatus* has a marked preference for human blood. This species was the commonest in the locality and there seems to be one generation per year with a peak in June. Adults began to appear in April and the last were caught in August. They were most active from half an hour before sunset through the night to early morning and did not travel far from their breeding places. Fourth stage larvae were found from November to July and pupae from April to July. Laboratory studies indicated that the eggs take two weeks to hatch, the larval stage lasts about five months (though some larvae may take as many as seven) and the pupal stage takes 5 days.

C. obsoletus appeared to feed more readily on rabbit's blood than did *C. impunctatus*. There seem to be two generations in a year with peaks in June and September. Eggs hatched within 3 days of laying, the larval stages lasted 3½ to 5 months and the pupal stage 5 days. The life cycle of a strain of this species reared in the field occupied six months in the summer and nine months during the winter.

The more limited observations on the other species indicate that they have but one generation in a year.

H. S. LEWIS

HILL, Marjorie A. & ROBERTS, Enid W. An Investigation into the Effects of "Gammexane" on the Larvae, Pupae and Adults of *Culex impunctatus* Goetghebuer and on the Adults of *Culex obsoletus* Meigen. *Ann. Trop. Med. & Parasit.* 1947 May, 41 No. 1 143-63 8 graphs. [10 refs.]

The experiments recorded in this paper were made in Knowles Park, Liverpool, in the summer of 1946. For the experiments on the immature stages, three sites were chosen in damp soil rich with humus, half shaded by rhododendron bushes. Sampling showed that each site contained a similar proportion of larvae and pupae and that they were present only in shaded portions, also that pupation commenced in May. The three plots were sprayed once, in May, one with 5 per cent. Gammexane in miscible oil plus lake water at 100 mgm. Gammexane per square foot, one with lake water only, and the other with miscible oil plus lake water.

Field tests showed no larvae or pupae in the Gammexane plot after thirteen days. In the control plots, the number of immature stages increased after the twentieth day until the seventy-seventh day (though there were no pupae after the forty third day) after the seventy-seventh day the number of larvae decreased until the 126th day the last of the experiment. No pupae from the "Gammexane" plot produced adults, but those from the controls produced 100 per cent. adults.

Laboratory tests of residual toxicity of soil samples from the 'Gammexane plot' showed a continuous increase in the time required to give a 100 per cent kill of larvae. In the first fortnight, twenty-four hours immersion was sufficient, but after the seventeenth week seven days' contact with the sample of treated soil was necessary to kill all larvae.

Soil penetration tests showed that Gammexane was present in a toxic concentration at a depth of one centimetre during dry weather, but effective penetration was increased to three centimetres after heavy rain and toxicity was still maintained even when the ground was water logged. However, toxic effects were never observed to extend to a greater depth than three centimetres.

Observations suggest that Gammexane on the soil surface has but a limited effect on ovipositing females and it is uncertain whether Gammexane exerts any ovicidal action or whether it kills young larvae as they hatch from the eggs. From the experiments with early stages, it is concluded that spraying the breeding places with 5 per cent Gammexane at 100 mgm per square foot in May not only destroys the generation of *Culicoides* about to emerge, but also prevents development of adults in the following summer.

In the tests against adults of *Culicoides* five black cloths, each $1\frac{1}{2} \times 2$ feet, were saturated with 75, 150, 300, 600 and 1 500 mgm of Gammexane in benzene to give deposits of 12.5, 25, 50, 100 and 250 mgm per square foot respectively, one other cloth was soaked in benzene only. The cloths were suspended 4 to 5 feet from the ground and left exposed for a month. Lighting midges were collected the first evening, starting one hour before sunset, and ten minutes were allowed for each cloth. Other evening collections were made on four occasions at intervals of six days.

It is shown that the cloth with the highest concentration of insecticide was effective in killing all lighting midges for one week, other treated cloths were less efficient. Toxicity was lost at a steady rate on all cloths, until by the third week it was negligible. It is therefore concluded that this method is not likely to prove satisfactory in the control of adult *Culicoides* except for about two weeks in a restricted area.

JENNINGS, D. W. A Laboratory Method of rearing Chiggers affecting Man (Acarina: Trombidulidae). Reprinted from *Ann. Entom. Soc. America*, 1947 Mar v 40 No 1 56-68, 4 pls. [10 refs.]

The author describes his successful experiments in rearing the North American species of *Trombidula*. He reviews earlier work, from which it appears that even the most successful experimenters could only maintain these mites for one generation and with a high mortality.

Three species are known to occur in the United States *Eutrombidula alfreddugesi masoni* and *betulae* (? *homonis*) of these the last is confined to the southern States and also occurs in Tropical America. The author generally started his breeding by putting down black cards and collecting unengorged larvae which walked on to them or he collected wild reptiles which were generally infested and allowed engorged larvae to drop off them. He found that under laboratory conditions larvae of the three species very readily attached themselves to snakes, lizards or turtles (*Terrapene*). The last-named are found to be the most convenient to handle. He also recovered wild larvae by staking out a turtle in a suitable place for a few hours.

In rearing the stages which occur in soil it is necessary to work at high humidity but to avoid condensation in which larvae may be drowned. It was found convenient to use a jam jar with the bottom removed and a plug of plaster of paris put in in its place. The jar was closed by a screw top through which the larvae did not escape a hole was drilled in it and plugged with wool. The actual rearing medium was either sterilized humus or loose sandy soil.

In these containers, nymphs and adults fed on eggs of *Aedes*. If the shell of the egg is moistened, the mite can pierce it and remove the contents in a few minutes. This is clearly an unnatural food, but the extreme neatness with which the mite carries out this task might suggest that eggs of some other insect are a normal food. The mites ate such large numbers of eggs that it was found very difficult to provide enough for the purpose. It seems that the female mites lay an average of about ten eggs per day much higher figure than had been expected. The reproductive potential must be high, for the author obtained about 6000 larvae during two months from a culture containing twenty-three females. The minimum time under which the life-cycle was completed was 50 to 70 days.

The paper contains a large amount of valuable detail. It is clear that the author has maintained these mites for several generations and produced very large numbers of larvae for experimental work. His methods have greatly reduced the amount of handling required and it seems that the mortality was low.

GOODWIN R. L. Evaluation of Pyrophyllite as an Insecticide Diluent. *J. Econom. Entom.* 1947 Apr v 40 No. 2, 270-73 3 figs.

Pyrophyllite is hydrous aluminum silicate $H_2O \cdot Al_2O_3 \cdot 4SiO_2$ formed by hydrothermic alteration of volcanic deposits. It is rather difficult to distinguish from talc (the molecules of which are similar but with 3 atoms of magnesium substituted for two of aluminium) except by the mineralogist's blowpipe test with the use of cobalt nitrate solution.

Pyrophyllite is widely used as a diluent for insecticides in powder form, but there is some controversy about its merits. Three points are important in this connexion —

- (1) Various other minerals are sometimes sold as substitutes (e.g. mica)
- (2) It is easily confused with talc.
- (3) Quartz is sometimes present as an impurity to the extent even of 25 to 30 per cent. This causes an abrasive effect which may have important bearing

on the insecticidal action of a mixed dust Other dusts used as diluents (e.g. talc or kaolin) also may contain quartz and it is important to consider this in making comparisons between these diluents

J R Busvine

GARNHAM, P C C **Mortality of *Aedes aegypti* feeding on Rabbits receiving Oral "Gammexane"** [Correspondence] *Nature* 1947, Aug 2, 156-7.

Previous workers have shown that insects may be killed by taking the blood of a mammal fed with DDT (LINDQUIST *et al*, *J Econom Entom*, 1944, v 37, 128) or Gammexane [DE MEILLON, this *Bulletin*, 1947, v 44, 469] The present investigation used *Aedes* mosquitoes to determine how long the lethal effect lasted, and the minimum effective doses

It was found that single doses of 40 mgm per kgm of Gammexane given to rabbits killed all *Aedes aegypti* subsequently feeding on them for about four days Lower doses were sometimes ineffective shortly after they were given to the rabbits, but later were insecticidal [This suggests that the concentration of Gammexane in the blood rose, up to twenty-four hours after it was swallowed] These lower doses were insecticidal for about two days only It was not feasible to go above doses of 40 mgm per kgm which caused convulsions and death in some rabbits The mosquitoes showed a marked dislike of feeding on treated animals, few did so and these took smaller blood meals than normal

J R Busvine

GRANETT, P & SACKTOR, B **Testing Tick Repellents and Observations of Phototropic Effects** *J Econom Entom* 1947, Apr, v 40, No 2, 259-63, 9 figs

In experiments on the efficacy of chemicals as repellents of adults and nymphs of the tick *Amblyomma americanum*, it was observed that the animals were apt to move towards the greater light intensity, i.e., they exhibited positive phototaxis [The authors' use of the word "phototropism" for this behaviour is to be deplored, as experimental workers restrict the term "tropism" to bending movements such as those exhibited by plants in response to light] Unless illumination is controlled, phototactic responses may greatly confuse work on repellents

Kenneth Mellanby

BRENNAN, J M **Preliminary Report on some Organic Materials as Tick Repellents and Toxic Agents** *Pub Health Rep Wash* 1947, Aug 8, v 62, No 32, 1162-5

Fifteen chemicals, including several found effective against other pests, were tested for repellency and toxicity to the ticks *Amblyomma americanum* (lone star tick) and *Dermacentor andersoni* (Rocky mountain wood tick) Most of the materials applied to socks, etc., gave 95 to 100 per cent protection for four weeks following treatment Rinsing in warm tap water, however, removed most of the protective effect

None of the compounds immobilized adult ticks confined on treated cloth within two hours, but several stopped nymphs in fifteen to thirty minutes

The materials included dimethyl and dibutyl phthalates, phenyl cyclohexanol and benzyl benzoate There were insufficient data to determine the most satisfactory repellent, but a mixture of phenyl cyclohexanol and butylacetanilide seemed most promising

HEWLETT P. S. & PARRIN R. A. The Formation of Insecticidal Films on Building Materials. II. Tests of the Efficacy of various Types of Pre-treatment. *Ann. Applied Biol.* 1947 May v 34 No. 2, 224-32, 1 fig

When the surfaces of building materials (brick, wood cement, etc.) are sprayed with insecticides to give a residual film, much of the liquid is absorbed into the more porous materials and the availability of the insecticide is lost. In a previous paper (PARRIN and HEWLETT *Ann. Applied Biol.* 1946, v 33 381) the authors showed that pre-treatment of the building surfaces allowed more effective and persistent films of DDT and pyrethrum to be applied.

In this paper further substances supplied by manufacturers were tested for pre-treatment effectiveness in improving film formation of pyrethrum in white oil P31. The flour beetle *Tribolium castaneum* was used as the biological indicator.

Thirty substances were subjected to preliminary tests and seven were examined more carefully. It was decided that the necessary qualities of the pre-treatment coating material were that it should be (1) relatively impermeable to the insecticide, and (2) wetted by the insecticide. The two most promising materials were 10 per cent. size and 5 per cent. gelatin—these will be examined further.

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

SOUTHERN RHODESIA. Report on the Public Health for the Year 1946 [MORRIS, R. M. Medical Director & Chief Health Officer] 50 pp. 1947 Salisbury Rhodesian Printing & Publishing Co. Ltd.

General—In April Dr. R. M. Morris took over the duties of Medical Director and Chief Health Officer from Dr. Martin who had held the position for 10 years. During 1946 the Commission under the chairmanship of Professor C. M. F. Saint, C.B.E., F.R.C.S. issued their report on the National Health, and another Commission, with Dr. A. J. Orenstein, C.B., C.M.G., C.B.E. as chairman reported on the Colony's leprosy services.

Two new medical stations have been opened—one at Antelope Mine for the Matobo Native District with a European community and over 80,000 Africans; the other at Karoi for the settlement there and for the Miami Mica fields and the African reserves of the Zambesi Valley.

Vital Statistics.—The figures for 1941 are inserted in brackets after those for 1946 for purposes of comparison. The European population at the end of June was 83,450 (69,330). Asiatics 2,940 (2,570). Coloured persons 4,590 (3,970). native Africans 1,687,000 (1,380,000). European births 2,147 (1,783). birth rate 25.7 (25.4). European deaths 697 (696). crude death rate 8.2 (10.0). infant mortality rate per 1,000 live births 30 (43) the lowest ever recorded in Southern Rhodesia. maternal deaths 4 (7). maternal mortality rate 1.9 (4.0). The chief causes of death among Europeans were heart disease and cancer and of infants premature birth and congenital malformations. Four of the 65 infant deaths were due to malaria.

Diseases.—There were no cases of smallpox among Europeans, but 181 among Africans, with only 1 death. pulmonary tuberculosis 36 cases, 3 deaths among Europeans, 323 cases, 89 deaths among the Africans showing how much greater is the fatality rate among the latter. Of the infective diseases of childhood, chickenpox heads the list with 824 cases, 247 Europeans and 577 Africans. Measles is next with 345 Europeans and 433 Africans. diphtheria 282 cases

(51 Europeans, all recovering, 231 Africans with 40 deaths) comes third, *whooping-cough* is fourth, but far behind the others, with 190 cases (84 and 106 respectively) and *typhoid fever* accounted for 108 (24 Europeans, 1 fatal 84 Africans, 9 fatal). There were 30 European and 16 African cases of *acute anterior poliomyelitis*, one death occurring in each group. *Scarlet fever* shows, as elsewhere in the tropics, the greater susceptibility of the European, there was only one African case to 62 European cases, but none was fatal. Admissions of Europeans for *malaria* numbered 1 116, the lowest for 5 years, and for *blackwater fever* 9, the lowest ever recorded in the Colony. It is hinted that this last may be due at least in part, to the scarcity of quinine and its replacement by mepacrine. *Luophiles gambiae* is the chief vector of malaria. A Research Unit has concentrated on *schistosomiasis*, carrying out treatment of patients and destruction of snails in the same area. Sodium antimony tartrate (SALT) is used, in three injections given slowly on one day only, to a total of 1 grain for each 20 lb body weight, designed to destroy the female worm and so stop egg-production. Some physicians gave larger total doses of 1 grain per 12 lb body weight, but this seemed to entail greater risk. No case of *plague*, human or rodent, has been reported. Thirteen cases of *trypanosomiasis*, 5 fatal, have been notified, the highest for 35 years all from the Zambesi Valley areas. At the beginning of the year there were 1,004 *leprosy* cases registered at the three institutions, Ngomahuru, Myemwa, and Mnene. Five of them were in Europeans. During the year 269 patients were admitted, 140 re-admitted, 84 discharged, 56 died and 51 deserted, leaving 1,222 on the register at the end of the year [not 1,223 as stated].

Hospitals—There are 14 Government hospitals, European admissions to them totalled 12 236 [elsewhere stated as 11 966], or 146 per mille, in 1941 the respective figures were 11,391 and 164. Maternity beds have been reduced to 118 by the closing of one private maternity home. Native hospital admissions totalled 36,311 and there is much overcrowding. Much medical aid is afforded by *nurse clinics*, of which there are 73 applications have constantly been made for more to be inaugurated. Inpatients at these numbered 71 620 and outpatients 245,138. Medical Mission clinics 37 in number, subsidized by the Government, provide 587 beds for Africans during the year, admissions to these totalled 29,657 and outpatients 166,399.

In the mines 70 545 were employed 1 284 fewer than in the preceding year, deaths 522 (564) were fewer and the rate 7.4 (7.85) per mille was lower. Venereal diseases are increasing both gonorrhoea and syphilis are common in the towns and the mining areas the main reservoir being native prostitutes. **Laboratories**—There are three routine laboratories all of which have done excellent work with a small staff assisted by Africans who have proved apt pupils at routine microscopical examinations. Details of the numbers of the different samples and specimens examined are given in lists in Appendices to the report.

Schools—There are three medical inspectors of schools and school children and a fourth is to be appointed when a suitable candidate can be found. There is a Government *Dental Service* with a staff of four qualified dentists whose time has been fully occupied in dealing with over 12,000 children and many other patients.

Health Inspectors do a vast amount of good work. Though there is only an establishment of 16, they inspect premises and supervise general sanitation, food and slaughter-houses. They perform vaccinations against smallpox (347,570 in the year) and against diphtheria (44,230). They have made 23,000 collections of mosquitoes. In some of these activities, they are assisted by Africans.

Nurses are overworked of a trained staff establishment of 145 only 126 are on the permanent staff nevertheless this is a great improvement on the previous year when there were only 65. To relieve the pressure, it has been found necessary to engage a number of midwives in the larger maternity homes although they have neither medical nor surgical qualifications. Training of nurses is carried on at Salisbury and Bulawayo hospitals of 50 candidates at the preliminary examination, 36 passed of 20 up for the final, all passed, 11 of them with honours. African males are also trained to become nursing orderlies, 31 presented themselves for the lower examination and all but two passed, as did 10 out of 11 at the higher examination.

i. PATERSON A. R. The Human Situation in East Africa. Part I. On the Increase of the People. Part II. Towards a Population Policy. *East Africa Med. J.* 1947 Feb & Apr v 24 Nos. 2 & 4 81-90 144 51

— Summary of some Figures and Opinions bearing on Population Growth. *Ibid.* 1947 Feb v 24 Nos. 2, 90-97

ii. *BRITISH MED. J.* 1947 Aug 9 14-15. Planning and World Population.

iii. MACDONALD G. Planning and World Population. [Correspondence.] *Brit Med J.* 1947 Sept. 27 506-7

I. These papers by former Director of Medical Services of Kenya form detailed consideration of the statements, quoted from the Governor of Kenya, that it is now evident that taken as a whole East Africa is barely able to support itself in food at the present time and that an ignorant man and his wife with a hoe are totally inadequate foundation for an enlightened state of society.

There is little doubt that the population of Kenya, and of East Africa as whole is now increasing at a rate which, if it persists, will present a continuously serious problem in relation to food, agriculture and soil productivity. The rate of increase has been estimated at between 1.5 and 2.3 per cent. per annum. These rates would raise the population of East Africa from just under 12,000,000 in 1935-6 to 34,000,000 or 50,000,000 respectively in 70 years. Public health measures and freedom from local internecine war will tend to remove certain checks on the growth of population, but the pressure of population unless it is accompanied by vigorous and enlightened agricultural policy will result in food shortage and its sequel, disease which would go far to neutralize public health effort.

Meanwhile according to the author the fertility of the soil of Kenya is declining by 50 per cent. we are told in the past twenty-five years. (The authority for this is not quoted, and to a reader the bald statements sometimes

made, that the soil of East Africa is naturally poor, are unsatisfactory in the absence of detailed information or proof.] The policy advocated by the author in the face of this most serious threat to the social and economic life of East Africa comprises a complete, synchronized and integrated policy of modernization such as was outlined by NOTESTEIN [this *Bulletin*, 1945, v 42, 507]. Eventually, the size of families among the Africans will need to be curtailed, but to preach that doctrine to Africans now would be to invite the comment that the object of limitation must be to exterminate them. Control of size of families must therefore be induced by indirect means, by general education and general improvement in conditions of life.

Details of the programme of modernization are quoted from Notestein's paper, but are too full for reproduction here, they include proposals for industrial development and for social advancement.

ii In the editorial article, similar points are made, and the papers of Paterson are quoted along with others on India and elsewhere. Again are stressed, in relation to East Africa, the three factors: exhaustion of fertility of the soil because of the absence of fallow, ignorance of satisfactory methods of agriculture, and the high rate of increase of the population. The editorial ends as follows: "Yet unless the birth rate falls in relation to the death rate and the population problem is solved much talk about colonial development and welfare is, to use an American expression, 'whistling in the wind'."

iii Macdonald takes exception to the point of view displayed in the editorial article referred to. He admits that at present rates of increase of population there will come a time when population pressure is too much for the capacity of the land, but he argues that so much of East and South-East Africa is undeveloped, and that so much could be developed with comparative ease if simple methods of tapping ground water were adopted on a sufficient scale, that to speak of reducing population increase is at least premature. He points out that population densities in East Africa vary from 41 to the square mile in Uganda to 5 in Northern Rhodesia, and that enormous tracts of country are uninhabited. "The population problem is one of balance, and the economy of grossly undeveloped countries can be improved more readily and more to the general advantage of the world by an increase in the supportive capacity of the land than by a restriction of population, though ultimately that must come."

Charles Wilcocks

CAROTHERS, J. C. **Age and Wisdom Teeth in Africans** *East African Med J* 1947, Aug, v 24, No 8, 304-6, 1 graph

Medical practitioners in East Africa are frequently faced with the problem of giving an opinion on the age of Africans. This may be a serious responsibility, especially in adolescents, since the law for many purposes regards the East African as being adult if he is apparently 18 years of age or older. Many factors are required in framing an opinion, but there are often great difficulties. If it could be found that wisdom teeth erupted with some constancy at certain ages in Africans, they might prove a useful guide.

The author counted the wisdom teeth of 150 African boys admitted to a High School in Kenya. Many of them claimed to know the date of their births, although the author admits that this unsupported evidence detracts from the value of the enquiry, he has no reason to doubt that they were speaking the truth.

The boys represented a fair sample racially of the population of Kenya. They were mostly between the 15th and 22nd years of life.

The development of the wisdom teeth is shown in a table and depicted in graphic form. From the evidence available, the author observes that "one might draw the following very tentative conclusions —

- " 1. The African's wisdom teeth erupt with some constancy between the 15th and 21st birthdays.
- " 2. If an African has no wisdoms he is unlikely to be more than 20 years old.
3. If an African has all his wisdoms he is unlikely to be less than 17 years old.
- " 4. If an African has some of his wisdoms only he is unlikely to be more than 20 or less than 15 years old.

[This form of enquiry merits further investigation on a wide scale, in the search for a solution to a problem so familiar and often so perplexing to medical officers in Africa.]

BOARD OF TRADE. German Industry. B.I.O.S. Final Report No. 1387 Tropical Medicine at Hamburg and Elberfeld. [Reported by F HAWKINS.] 26 mimeographed pp., 3 diagrams. 1947 London H.M. Stationery Office. [2s. 6d.]

WAMYONGI L. L. Contribución al estudio del problema de saneamiento en Venezuela. [The Health Problem in Venezuela.] XII Conferencia Sanitaria Panamericana. Cuadernos Amarillos. Publicaciones de la Comisión Organizadora. No 28 Caracas. 1946 70 pp. numerous charts, figs. & maps.

Venezuela is a country of 912,050 sq. kilometres and a population, in 1941 of 3,849,919. The density of population varies greatly but is well shown in sketch map with varying shading. During the quinquennium 1940-44 the chief causes of death were diarrhoea and enteritis [the former is rather a symptom than a disease] tuberculosis, heart disease, pneumonia and malaria. About 5 000 deaths occur annually from "water-borne" diseases—enteric fever or dysentery (amoebic and bacillary) and infantile diarrhoea.

The Ministry of Health and Social Assistance was created in March 1936 and a Division of Malariology the same year and of Sanitary Engineering in 1937. In 1942 a Division to deal with the hookworm question was set up. The need for the last will be clear when we are told that *Necator* infestation ranges between 17 and 91 per cent., with an average for the country of 52 per cent. that a census of houses revealed that of a total of 668,838 there were 509,306, or 76 per cent. without any arrangement for disposal of excreta. Details of faecal examination of over 13 000 specimens in 46 localities are given in a table, in 8 localities every specimen revealed a positive result and in 29 other localities there were 91-99 per cent. positive. A series of graphs shows the prevalence of this and other helminths in the different districts.

AVOIDABLE MENINGITIS

MEMORANDUM DRAWN UP BY THE PUBLIC HEALTH LABORATORY SERVICE AND
THE LONDON SECTOR PATHOLOGISTS' COMMITTEE *

Every operative procedure entails some risk to the patient, but in simple operations like spinal puncture the risk ought to be practically negligible. The occurrence of meningitis following the withdrawal of cerebrospinal fluid or the administration of a spinal anaesthetic is a grave reflection on the methods used in many hospitals, because these "accidents" can be avoided by the adoption of a simple and reliable technique. That such a technique is not in fact universally employed is attested by the number of cases of avoidable meningitis reported in the literature during the past few years. Furthermore, as Garrod (1946) points out, "There is a natural reluctance to publish anything which may appear discreditable. It is therefore probable that meningitis following spinal anaesthesia has been far commoner than the literature of the subject would suggest." This statement is endorsed by surgeons and anaesthetists whenever the subject comes up for discussion.

Nature and Sources of Infection

This memorandum is not concerned with meningitis secondary to some primary infective focus already present in the patient at the time of operation. It refers solely to meningitis that results from the direct inoculation of micro-organisms into the spinal canal. The organisms most frequently incriminated are *Ps. pyocyanea* and related organisms which can multiply in water at room temperature, less frequently staphylococci and other skin contaminants may be responsible. Some of the water bacteria fail to grow in ordinary culture media incubated at 37°C, hence many cases have been diagnosed as irritative or aseptic meningitis which were probably the result of bacterial infection of the meninges. Organisms normally regarded as non-pathogenic may produce infection if they gain access to the very susceptible meninges.

The sources of contamination may be listed as follows —

- (1) Apparatus inefficiently sterilized or contaminated during use
- (2) "Sterile" water or saline used to rinse the apparatus
- (3) Hands of operator and assistants
- (4) Skin of patient
- (5) Anaesthetic, antibiotic or other solutions

[* This memorandum supplements the recommendations of the Medical Research Council in their report (War Memorandum No 15) on 'The Sterilization Use and Care of Syringes' (see this *Bulletin* 1945, v 42 843). Certain minor changes in the wording of two sentences have been made with permission, in view of the special interests of readers of this *Bulletin*. Ed.]

Precaution Measures

The ideal would be to adopt the full aseptic ritual of a surgical operation for every spinal puncture. In many cases the time and place render this impossible. The following recommendations are therefore offered, not necessarily as ideal procedures but as practical methods applicable in nearly all circumstances.

(1) *Apparatus*.—If facilities are available, all apparatus including manometer should be enclosed within suitable containers and sterilized either by autoclaving at 15 to 20 lb. pressure for 20 minutes or by dry heat at 160°C. for an hour. The complete outfit can then be held ready for use at any time. If dry heat is used, the rubber tubing of the manometer should be sterilized by boiling. For syringes and needles dry heat is preferable but ordinarily necessitates the use of all-glass syringes. (Glass syringes with metal needles, which will withstand dry heat at 160°C. for 2 hours are now being manufactured.) Full details of these methods, together with recommendations for a hospital syringe service, are given in the Medical Research Council's War Memorandum No. 15 (1945) on "The Sterilization, Use and Care of Syringes".

If autoclaving or dry heat sterilization cannot be employed, all apparatus should be sterilized immediately before the operation by boiling for 5 minutes, preferably in distilled water. A sterilizer with a perforated lift-up tray should be used. At the end of boiling the tray is removed, placed in the inverted lid, covered with a sterile towel and left to cool.

In the occasional emergency which may arise in the patient's home a perfectly clean saucepan with a lid may be used. After boiling, the water should be drained off and the saucepan left with the lid on until cool. Methods of chemical disinfection such as soaking in spirit should not be used.

(2) *Sterile Water and Saline*.—These probably constitute the greatest source of danger. Hospital supplies are frequently contaminated either from inadequate sterilization initially or from contamination during previous use (SMITH and SMITH, 1941). Thus the Winchester bottle of sterile distilled water or saline, used repeatedly until empty, has frequently been incriminated as the source of water bacteria found in contaminated or infected cerebrospinal fluid. *If apparatus is sterilized as recommended above rinsing and cooling solutions become quite unnecessary and their use should be abandoned.*

(3) *Hands of Operator*.—The operator should scrub up as for a major operation, or alternatively should don dry sterile surgical gloves. When gloves are not available it is important that his hands be dry before he handles any apparatus: this may be accomplished by rinsing with industrial spirit and/or drying with a sterile towel. Where needle and syringe have to be assembled, the needle should be handled with sterile forceps. From this point onwards the operator should touch nothing except the sterile instruments and the skin of the patient until the operation is finished. The trocar when withdrawn should be laid on a sterile towel: otherwise it may infect the spinal fluid if it is introduced again to clear the needle.

(4) *Skin of Patient*.—Thorough washing with soap and warm water followed by thorough, not perfunctory, swabbing with tincture of iodine or 70–80 per cent. alcohol will leave little risk of contamination of the needle by the patient's skin. The area treated should be the entire area exposed and the skin should be quite dry before puncture is made.

(5) *Anaesthetic and Antibiotic Solutions*.—No cases of meningitis have been traced to the presence of bacteria in anaesthetic solutions contained in sealed glass ampoules. Such ampoules are preferable to rubber-capped bottles intended for repeated use.

The sterilization of the outer surface of an ampoule is difficult and attended with such pitfalls that it is better not to attempt it. The ampoule should be

opened, after swabbing the neck with 70 per cent alcohol applied with sterile swabs, by an assistant whose hands have been scrubbed and dried. It may be held in a sterile towel or piece of sterile lint. The operator must then introduce the needle of the syringe into the ampoule without fouling the mouth.

Other forms of container should be avoided except where absolutely necessary. If a rubber-capped bottle has to be used, it should be held in a sterile towel by the assistant, and the cap should be thoroughly swabbed with 70 per cent alcohol or tincture of iodine. It is unwise to use rubber-capped bottles for more than a short time, and they should be replaced frequently, or, if the contents permit, returned to the central sterilizing depot each day for complete sterilization by an appropriate method.

The intrathecal injection of antibiotics such as penicillin and streptomycin demands the same high standard of aseptic technique, and all precautions should be taken to ensure that the solutions themselves are sterile.

Reporting of Cases

The general adoption of the measures recommended here would, without doubt, reduce the incidence of "accidental" meningitis but would not close every possible loophole for infection. Further safeguards can be found only if cases are thoroughly investigated as and when they occur and with the employment of specialized bacteriological methods. The Public Health Laboratory Service will willingly co-operate with the hospital pathologist or other officer in carrying out such investigations as are required.

Gratitude is expressed to Sir Hugh Cairns and Professor Wilson Smith for the help they gave in the preparation of this memorandum.

SUMMARY OF RECENT ABSTRACTS*

II YELLOW FEVER

General

CECCALDI (p 75) reports that a small experiment suggested that penicillin may have some slight virucidal action on the yellow fever virus.

PERLOWAGORA and HUGHES (p 657) discuss a complement-fixation test for yellow fever, in which they have used the globulin fraction of a mouse-brain antigen. This test becomes positive after even mild attacks of yellow fever, but rarely after vaccination with 17D. It should prove useful in epidemiological studies, for tracing comparatively recent cases of yellow fever.

Epidemiology Epizootology Transmission

MAHAFFY *et al* (p 72) have brought together the results of mouse-protection tests performed on sera from various parts of East Africa, which have helped to define the areas in which yellow fever has occurred recently. These areas extend from the Belgian Congo to the Sudan and Eritrea, as far south as Northern Rhodesia, over a far wider area than would be suspected on the

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947 v 44. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

evidence of clinical diagnosis. The authors point out the important fact that a high proportion of cases in Africans are mild, and that mild yellow fever cannot be diagnosed clinically.

HADDOW *et al.* (p. 892) state that continuous studies made in Uganda have shown that, of the many groups of animals investigated, yellow fever immunity is found only in monkeys. The important species in this respect are *Cercopithecus mitis* *impans* and *Colobus polykomos nallensis*. The species of mosquitoes chiefly suspected of transmission from monkey to monkey are mainly arboreal, and investigations indicate that *Aedes africanus* may be the principal vector in this animal community. It seems likely that the *Colobus* monkeys are the chief species involved in the monkey-to-monkey cycle in uninhabited forest areas, but that the *Cercopithecus* monkeys are important in bringing the virus into contact with man. SMITHBURN and HADDOW (p. 71) have found yellow fever virus in wild-caught *Aedes simpsoni* and in *Aedes* of other species (excluding *aegypti*) in Western Uganda. They give reasons for thinking that *Aedes africanus* may be implicated. There is apparently an extra-human cycle of yellow fever in monkeys and mosquitoes in the Semhki forest. HADDOW *et al.* (p. 516) have investigated the vertical distribution and the biting cycle of mosquitoes in an area of rain-forest in Uganda. Catches were made up to 80 feet from the ground, and the mosquitoes caught were identified, pooled, and injected into monkeys to test for yellow fever virus. This was found in only one batch of *Aedes* species, containing, among others, *Aedes africanus*, a known potential vector. *Aedes africanus* is the commonest arboreal culicid, and is most abundant 50-80 feet from the ground. In the area studied the monkey population is about 400 to the square mile. The authors give much information on temperature and humidity and on the biting-times of the various mosquitoes. They note that *Anopheles gambiae* is by far the commonest mosquito even far from human haunts.

BAILEY (p. 657) reports a study of the sylvan mosquitoes of Gede, a settlement in forest country on the coast of Kenya. *Aedes* species haunt the upper forest strata.

LEWIS (p. 656) gives much general information on mosquitoes of the Sudan in relation to yellow fever and includes a list of the known vectors but the paper cannot satisfactorily be abstracted further. Mosquito control in the Sudan has rendered impossible an urban epidemic transmitted by *Aedes aegypti* and has eliminated this mosquito from the river steamers.

DURRIX *et al.* (p. 901) found protective antibodies in 88 per cent. of a series of baboons (and one other monkey) in French territory near the Gambia. They note that the percentage usually recorded is of the order of 20-25 per cent., and they make the point that further investigation indicated that the positive results could not be explained by the presence of non-specific substances in the sera. Wild animals are evidently important as reservoirs in this part of Africa.

TAYLOR *et al.* (p. 414) undertook an extensive investigation in the State of Bahia, Brazil, in which they found evidence of jungle yellow fever spreading to man in the absence of *Aedes aegypti*. Positive neutralization tests were found in man, most commonly in adult males who frequently visited those forests which are more than 75 years old. Many mammals and mosquitoes were collected and tested, but although protective bodies (which were probably not specific) were found in certain rodents, the only definite evidence of transmission was in relation to marmosets (of which four *Callithrix jacchus* were found with circulating virus) and *Haemagogus papuanus* (from which virus was obtained). There is, therefore, a close relationship between immunity in man and marmosets, the prevalence of *Haemagogus* species, and the older climax type of tropical rain-forest. WADDELL and TAYLOR (p. 309) think that the marmosets *Leontocercus chrysomelas* and *Callithrix jacchus* are the principal,

if not the sole, vertebrate hosts of the yellow fever virus in part of the State of Bahia, Brazil

BATES and ROCA-GARCIA (p 310) think that the opossums *Metachirus* and *Caluromys* are the two most susceptible Colombian marsupials, but even with these, infection of *Haemagogus* mosquitoes is difficult, so that it is doubtful if the local marsupials are important in the *Haemagogus* cycles in nature. On the other hand, the cycle was easy to maintain with certain monkeys and marmosets [but see below]. ANDERSON and ROCA-GARCIA (p 992) show that the opossum *Caluromys laniger* is susceptible to infection with yellow fever virus, although the infection is not fatal. After injection of virus, in most cases the virus circulates in the blood for several days, and specific neutralizing antibodies appear later. Some of the animals maintain the neutralizing antibodies, but in others the antibodies decrease and may disappear, in which case the animal may once more become susceptible to infection. Certain anomalies were found in a proportion of the animals, in relation to infection and immunity, but the majority reacted as described.

ANDERSON and OSORNO-MESA (p 309) note that other workers have shown that *Haemagogus spegazzini falco* and *H. equinus* are capable of transmitting yellow fever virus, and report that they themselves have proved *H. splendens* also to be capable of transmitting the virus under laboratory conditions. BATES and ROCA-GARCIA (p 308) have noted that *Haemagogus* mosquitoes fed on Saimiri monkeys infected with a pantropic strain of yellow fever virus rarely become infected themselves, and in a series of experiments with French neurotropic virus passaged in Saimiri monkeys, they failed to demonstrate infection in any of the *Haemagogus* mosquitoes subsequently fed on them.

In a study of the infection of *Haemagogus* mosquitoes with yellow fever virus, the same authors (p 415) have shown that the virus diminishes in amount in the mosquitoes for a few days after ingestion, and may even die out altogether, but that multiplication then takes place very slowly, and the mosquito may become infective by bite 10-28 days after infection. These processes depend very largely on the environmental temperature, and the temperature range found in nature in the haunts of *Haemagogus* species not only favours the development of the mosquitoes, but also of the virus in them.

SNIJERS *et al* (p 993) report on protection tests carried out in Surinam, where they indicate the presence of jungle yellow fever.

KOPROWSKI (p 580) comments on the fact that the sera of various animals have shown virucidal properties against the yellow fever virus, even though the animals have never been infected. He shows that many of these sera are virucidal also to certain other viruses which are not found in the countries concerned. This non-specific virucidal property is transitory, and the animals concerned react specifically to injection of yellow fever virus.

Vaccination

FOX (p 1062) has studied the factors which influence the multiplication of virus 17D in tissue cultures, but details of his findings must be sought in the original. FOX and LAEMMERT (p 1062) report observations on the infection of developing chick embryos, but these again must be sought in the original. They make the point that prolonged embryo-to-embryo passage of strain 17D, and the French neurotropic strains, did not reveal significant changes in the character of the virus. It is still unknown by what means the attenuated variants of yellow fever virus (such as 17D) may be produced, continuous embryo passage usually fails to produce them.

BURRUSS and HARGETT (p 994) have found that 17D vaccine virus may be desiccated at room temperature without more loss than occurs at lower temperatures, but they advise that it should then be stored at -20°C to -25°C .

Adequately desiccated vaccines may remain potent enough for use even if kept at tropical temperatures for a few weeks, but great loss of virus does take place under these conditions. When the vaccine is diluted for use, 1:1 or 1:10 dilutions should be used within one hour and 1:100 within 10 minutes.

PALTIER (p. 417) describes the preparation of the dry mouse-brain vaccine made in Dakar. The brains of mice which have been inoculated intracerebrally and which show paralysis, are desiccated, ground with an inert powder and kept at -4°C . to be reconstituted, for scarification, with a gum solution. This vaccine is sometimes mixed with smallpox vaccine. LAHORRIE (p. 580) does not approve of the mixing of smallpox and yellow fever vaccines, for scarification, because he believes that the neurotropic properties of each may thus be enhanced.

In the *Epidemiological Information Bulletin* (UNRRA Health Division) (p. 73) there is a detailed account of a series of comparative tests of the neurotropic brain vaccine made at Dakar and administered by scarification, in a gum solution with or without smallpox vaccine and of the American 17D vaccine given subcutaneously. The Dakar vaccine was undoubtedly a potent immunizing agent, producing neutralizing antibodies in the serum of practically 100 per cent. of the subjects tested. But vaccine 17D also produced neutralizing antibodies in practically 100 per cent., and it has shown itself to be a powerful immunizing agent in the field. 17D does not produce encephalitis, which has been reported after the use of mouse-passage neurotropic vaccine used without immune serum. Each of these vaccines is unstable at temperatures above 5°C . but can be kept for long periods if dried and frozen. In a long comment on this paper MACCALLUM discusses the history of yellow fever vaccination. The intraperitoneal mouse-protection test appears to be more sensitive than the intracerebral test, in detecting neutralizing antibodies.

ANDERSON and GAST-GALVIS (p. 813) have investigated the state of immunity of people vaccinated about 5 years previously in Colombia. They found evidence of neutralizing antibodies in some 93 per cent., and show that there is no essential difference in response between children and adults. They conclude that revaccination is not usually necessary within 5 years of vaccination with 17D.

Control

FINDLAY (p. 579) discusses the spread of yellow fever and other diseases by aircraft and suggests that an international organization should be formed under the W.H.O. to control airfields, disinsection of aircraft, yellow fever vaccine and vaccination certificates.

DE CALLES (p. 638) reports on the yellow fever service of British Guiana. He considers that DDT is one of the very important means of controlling *Aedes aegypti* but that much investigation remains to be done, for instance in relation to the ability of eggs of this mosquito to remain viable for long periods in dry conditions. In a later report (p. 604) he states that this service has now ceased to exist as a separate organization, having become part of the mosquito control service. The value of DDT is again emphasized, but control depends chiefly on a high standard of efficiency in all branches of the service, which has been attained. No case of yellow fever was reported in the Colony during 1948.

ZOTTA, G, RADACOVICI, E, TEODORESCU, A M, GEORGESCU, M, MARDARE, I, DUPORT, M, ATANASIU, M & TRIFON, A Evoluția endemiei palustre în județul Teleorman [The Course of a Malaria Epidemic in Teleorman]
Rev Sinfelor Med Bucharest 1946, Sept-Dec, v 36, Nos 9/12, 781-815, 9 graphs & 1 map French summary

Teleorman is on the left bank of the Danube between 1935 and 1942, there was an epidemic of malaria, in two phases, the first (1935-1938) was of moderate intensity and constant extent, the second (1939-1942) was more severe

In general, cases were seen mostly in river valleys and particularly those of the rivers Urlui, Calmatzuu and Teleorman, in the lower parts of which the flood areas of the Danube may also be included

The serious nature of the epidemic during the war years may be attributed, not only to war conditions, but to natural factors and also to man-made causes, particularly that of rice cultivation which was a recent introduction All along the rivers, the local inhabitants had constructed dams, which resulted in the formation of breeding places for mosquitoes

All human species of *Plasmodium* were found, except *P ovale*, the proportions varied each year In general, *P vivax* infections were commoner than those caused by *P falciparum*, except in 1936 (*P vivax* 624, *P falciparum* 772) and 1939, when the numbers were about equal (1,373 and 1,334) Quartan was rarely seen, and in 1939 was not reported at all

Although all varieties occurred together throughout the year, each showed a definite seasonal period of spread, *P vivax* was prominent in spring and summer, *P falciparum* at the end of summer and throughout the autumn, and *P malariae* in the colder months

All types of *Anopheles maculipennis* found in Rumania, on the left bank of the Danube, constituted insect vectors, namely *A m messae*, *A m atroparvus*

Adequately dedicated vaccines may remain potent enough for use even if kept at tropical temperatures for a few weeks, but great loss of virus does take place under these conditions. When the vaccine is diluted for use, 1:1 or 1:10 dilutions should be used within one hour and 1:100 within 10 minutes.

PALTIER (p. 417) describes the preparation of the dry mouse-brain vaccine made in Dakar. The brains of mice which have been inoculated intracerebrally and which show paralysis, are desiccated, ground with an inert powder and kept at -4°C . to be reconstituted, for scarification, with a gum solution. This vaccine is sometimes mixed with smallpox vaccine. LAIGRET (p. 580) does not approve of the mixing of smallpox and yellow fever vaccines, for scarification because he believes that the neurotropic properties of each may thus be enhanced.

In the *Epidemiological Information Bulletin* (UNRRA Health Division) (p. 73) there is a detailed account of a series of comparative tests of the neurotropic brain vaccine made at Dakar and administered by scarification, in a gum solution with or without smallpox vaccine, and of the American 17D vaccine given subcutaneously. The Dakar vaccine was undoubtedly a potent immunizing agent, producing neutralizing antibodies in the serum of practically 100 per cent. of the subjects tested. But vaccine 17D also produced neutralizing antibodies in practically 100 per cent., and it has shown itself to be a powerful immunizing agent in the field. 17D does not produce encephalitis, which has been reported after the use of mouse-passage neurotropic vaccine used without immune serum. Each of these vaccines is unstable at temperatures above 5°C . but can be kept for long periods if dried and frozen. ZOTTA, G., RADACOVICI, E., TEODORESCU, A. M., GEORGESCU, M., MARDARE, I.,
DUPORT, M., ATANASIU, M. & TRIFON, A. **Evoluția endemiei palustre în județul Teleorman** [The Course of a Malaria Epidemic in Teleorman]
Rev Stinfelor Med Bucharest 1946, Sept-Dec, v 36, Nos 9/12,
781-815, 9 graphs & 1 map. French summary.

Teleorman is on the left bank of the Danube. Between 1935 and 1942, there was an epidemic of malaria, in two phases, the first (1935-1938) was of moderate intensity and constant extent, the second (1939-1942) was more severe.

In general, cases were seen mostly in river valleys and particularly those of the rivers Urluiu, Calmatzuu and Teleorman, in the lower parts of which the flood areas of the Danube may also be included.

The serious nature of the epidemic during the war years may be attributed, not only to war conditions, but to natural factors and also to man-made causes, particularly that of rice cultivation which was a recent introduction. All along the rivers, the local inhabitants had constructed dams, which resulted in the formation of breeding places for mosquitoes.

All human species of *Plasmodium* were found, except *P. ovale*, the proportions varied each year. In general, *P. vivax* infections were commoner than those caused by *P. falciparum*, except in 1936 (*P. vivax* 624, *P. falciparum* 772) and 1939, when the numbers were about equal (1,373 and 1,334). Quartan was rarely seen, and in 1939 was not reported at all.

Although all varieties occurred together throughout the year, each showed a definite seasonal period of spread, *P. vivax* was prominent in spring and summer, *P. falciparum* at the end of summer and throughout the autumn, and *P. malariae* in the colder months.

All types of *Anopheles maculipennis* found in Rumania, on the left bank of the Danube, constituted insect vectors, namely *A. m. messae*, *A. m. atroparvus*

and *A. m. maculipennis*. The first-named occurs in the southern flood-region where stagnant water is in evidence. Its rôle as a malaria vector is important, though not striking.

A. m. atroparvus is found throughout the Department wherever the soil is salty and the water covering it becomes brackish. It plays a predominant part in transmission throughout the year.

A. m. maculipennis is predominant in the northern half of the Department. While it is not in general regarded as a vector, it must be suspected to play an important rôle among a population who are so much exposed to it outdoors where they sleep in the summer without providing themselves with any protection against it.

H. J. O'D. Burke-Gaffney

SIRTS G & TWINKING May. Survey and Field Treatment of Malaria in Mauritius. pp. v+76, 50 figs. & 5 pls. 1948. Published on behalf of the Government of Mauritius by the Crown Agents for the Colonies. London: 4 Millbank, S.W.1 (25/- or Rs. 16.67)

This is the most comprehensive survey of malaria in Mauritius yet published. The survey was undertaken at the request of the Military Authorities when it became necessary in 1942, to post troops and labour gangs in certain of the coastal areas where malaria was rife. The detailed work of the survey was carried out by three V.A.D. assistants and three male laboratory assistants. In assessing the incidence of the disease children from two to ten years of age were examined. To study the development of immunity babies from birth to two years of age and persons from eleven to twenty years of age were examined.

Mauritius is an island of volcanic origin, 700 square miles in extent with a high central plateau. In the north and south-east there are large areas below the 600-feet level elsewhere the coastal plain is narrow. At high altitudes the annual rainfall exceeds 150 inches. There are numerous small rivers and streams, and irrigation canals for sugar cane. In the coastal belt the drainage is poor. The population is about 400 000 (600 to the square mile) 70 per cent. of whom are Indians.

Malaria-carrying mosquitoes were introduced into Mauritius in 1865 either from Madagascar or from East Africa. The result was devastating. In 1866 the death-rate for the whole island was 32.1 per thousand. In 1867 it rose to 120.5 per thousand. It was, however, not until 1869 that the disease completely encircled the island. Since then malaria has been very largely confined to the coastal belt. It was so when Ronald Ross made his survey in 1908. Small outbreaks of great intensity have occurred, however, from time to time at higher altitudes. Thus at Alma, 1,500 feet, a severe outbreak occurred during the first quarter of 1943 when a thousand cases were notified in a camp with a strength of 1,200. The spleen rate was 90 per cent.

The two malaria vectors are *A. gambiae* and *A. funestus*. *A. maculipennis* is only occasionally found. *A. mauritianus* [*A. costanti*] has not been shown to be a vector.

The average spleen rate of children living below 600 feet was 48 per cent. from 600 to 1,200 feet, 13. from 1,200 to 1,800 feet 8 (excluding Alma, on the occasion mentioned above) above 1,800 feet 7. Fifty nine per cent. of the population live below 600 feet, this area constituting a little more than half the total area of the island.

Below 600 feet the average parasite index was 36 per cent. (*P. falciparum* 48, *P. vivax* 35, *P. malariae* 32, mixed infections 14 per cent.). Above 600 feet, the parasite index was 12 per cent. (*P. falciparum* 40, *P. vivax* 43, *P. malariae* 21, mixed infections 16 per cent.)

Temperature appears to be the limiting factor in malaria transmission, there is but little transmission even at sea level in the winter. The breeding of *A. gambiae* may, however, occur as high as 1,500 feet when conditions are particularly suitable. The malaria "season" extends from December or January to the beginning of June.

A large proportion of the Mauritius population have a very poor nutritional standard, this probably accounts in part for failure to develop immunity. The maximum spleen rate in hyperendemic areas is reached at the age of five, very little reduction in spleen rate and no reduction in spleen size is seen even up to the age of 20. The parasite rate shows a very rapid rise to the age of four, thereafter there is a gradual decline. By the age of 14 it has fallen to half. The gametocyte rate curve corresponds with the parasite rate curve. Children between one and eight are the main danger to the community.

An interesting part of the report deals with the relationship between malaria and malnutrition. In villages with spleen rates below 20 per cent, nutrition was unsatisfactory in 2.4 per cent of children and borderline in 11.9 per cent. In villages with spleen rates above 20 per cent, nutrition was unsatisfactory in 6.8 per cent of children and borderline in 20.3. The commonest signs of malnutrition were mosaic skin, angular stomatitis and glossitis, and anaemia of the macrocytic type. Thirty per cent of children with enlarged spleens showed macrocytosis.

In the Black River District, where nearly all villages have spleen rates of 90 per cent or over, the infant mortality rate was 303 per 1,000 live births. In the Plaines Wilhems District, parts of which are almost malaria-free, the infant mortality rate was 114 per thousand.

As an emergency measure, children living in proximity to military areas were treated by a combination of drug therapy or extra feeding or both. When transmission was not excessive and nutrition was satisfactory, adequate control was secured with either quinine or atabrin [mepacrine]. Supplementary feeding with milk markedly increased the efficacy of drug treatment. Shark liver oil and yeast were also of value. Vegetable soup and yeast alone were both ineffective.

Norman White

SAUNDERS, G. M. & SCOTT, V. *Preservation of Plasmodium vivax by Freezing*
Science 1947, Sept 26, 300-301

Protozoa, unlike viruses, are difficult to preserve for long periods in an unchanged condition. Low temperature freezing, however, has been successfully employed up to 70 days in the case of animal plasmodia. The authors use such a method for the preservation of *Plasmodium vivax*. The infected blood is taken into 4 per cent sodium citrate solution, in the proportion of 20 parts blood to 3 parts citrate. About 2-3 cc. of the citrated blood are put into small, plastic, screw-capped vials and the blood is rapidly frozen at a temperature of -75°C by immersion in a mixture of alcohol and dry ice, then stored in a dry-ice box at -50°C . Before use, the blood is thawed in a water-bath at a temperature of 40° - 42°C . In this way, parasites remain viable up to 15 days or more and, in one case, up to 37 days.

The results indicate some modification from the normal in the ensuing infection, including, in at least one of 3 cases, a mild chill after inoculation. However, changes are only to be expected when it is considered that freezing and thawing cause almost complete haemolysis of the red blood cells and considerable modification in the staining reactions and morphology of the parasites.

MOSSA, E. Un nuovo metodo di produzione in vitro del processo di flagellazione dei microgametociti dei parassiti malarigeni. [Flagellation of Microgametocytes of Malaria Parasites in vitro.] *Riv di Parasit.* Rome, 1947 Mar v 8, No. 1 63-5.

Two or three drops of blood are removed from the comb or from a vein of the wing of a fowl infected with *Plasmodium gallinaceum* on to a slide and mixed with an equal quantity of a 3 per cent. solution of citrate of sodium. By rocking the slide, a homogeneous mixture is obtained. A very thin cover glass is placed on the mixture in such a manner that no pressure is applied. On examining the preparation microscopically it will be noted that the red cells arrange themselves in a floral design the centre of which will be found to be a flagellating microgametocyte. The observations were repeated with human blood containing *P. vivax* but the floral arrangement was not so marked as in the case of fowl's blood. As a modification of the method, the blood can be taken into a syringe containing the citrate solution and the mixture run on to the slide for observation. C. M. IVESON

PAL, R. Marking Mosquitoes with Fluorescent Compounds and Watching them by Ultra-Violet Light. [Correspondence.] *Nature* 1947 Aug 30 298-9.

The author has shown that mosquitoes (*Anopheles maculipennis* var. *atroparvus*, *Culex molestus* and *Aedes aegypti*) are not adversely affected by ultra-violet light, that they can take up enough fluorescent dust (anthracene and other substances) on their bodies to enable them to be observed at a distance of 10 feet in ultra-violet light, and that they are not adversely affected by the dust. Observations are therefore possible on the behaviour of mosquitoes at night which could not otherwise be made. Charles WILCOCKS

CHELĂRESCU M. & CURPAN C. Varietățile de *A. maculipennis* din regiunea Sibiului, județul sibiu. (Lucrare făcută sub conducerea Prof. M. CIUCA și Prof. L. BALLIF) [Types of *Anopheles maculipennis* in the Sibiu Region (Rumania).] *Rev Sănătății Med.* Bucharest. 1947 Jan.-Apr v 36, No. 1/4 63-75. French summary (8 lines)

Studies made in August 1944 in a malaria-free area of the Sibiu region showed the following prevalence of anophelines: *Anopheles maculipennis maculipennis* 63.3 per cent. *A. m. succus* 31.9 per cent. *A. m. atroparvus* 2.7 per cent. Examination of eggs also demonstrated the occasional presence of eggs having a different external configuration.

The first two species, when infected experimentally proved to be more resistant than homologous species from a hilly area (Socola-Lăpș).

UNGUREANU E. & SMITH, P. G. The Value of the Wing Scales as an Aid to the Taxonomy of Adult *Anopheles maculipennis*. *Proc. Roy. Entom. Soc. London* Ser. B. 1947 Aug 15 v 16, Pts. 7-8, 79-85 1 pl. [10 refs.]

A paper by Ungureanu (1944) on the wing scales of the *Anopheles maculipennis* complex has already been noticed (this Bulletin 1947 v 44 357). The material on which the present studies were based was obtained from Rumania, England, Algeria, Holland and Italy—the collection from Albania in the London School of Hygiene and Tropical Medicine was also examined.

From the accumulated data on shape and size of wing scales, the authors have been able to construct a key which they claim is 90 per cent. accurate, for the identification of *A. maculipennis atroparvus succus maculipennis* and

clutus (sacharovi) It is not yet possible to distinguish the larvae of these races except *clutus*, but keys are given for the separation of the eggs of the above and *labranchiae*, and for the identification of the males, the latter being based on details of the hypopygia

In view of the biological and morphological facts now known, the authors consider that the *A. maculipennis* group consists of at least four species rather than of varieties, *A. labranchiae* is not included yet, because sufficient material has not been studied and it can only be separated from *atroparvus* on egg characters. The wing scales of *A. m. maculipennis*, *atroparvus* and *messae* are shown in a photograph

MATTINGLY, P F Notes on the Early Stages of certain Ethiopian Mosquitoes, with some Locality Records from British West Africa *Ann Trop Med & Parasit* 1947, Sept, v 41, No 2, 239-52, 4 figs [20 refs]

This paper contains a description of the larva and pupa of *Anopheles domicolus* and some corrections and additions to existing descriptions of the pupae of *A. wilsoni*, *A. nlt*, *A. hargreavesi*, *A. argenteolobatus* and *A. multicolor*. Some points of difference between the larvae and pupae of *A. turkhu* and *A. hispaniola* are given and there is a note on the unreliability of the various criteria for distinguishing the larvae of *Aedes grahami* from other members of the subgenus *Mucidus*

The locality records include anophelines and culicines collected in British West Africa between September 1942 and December 1944, but do not include new records of anophelines already published by the author in 1944 [this *Bulletin* 1945 v 42, 434]. The present new distribution records are indicated in the concluding notes on species

GELFAND H M Natural Malaria Infection in *Anopheles rufipes* (Gough) *J Trop Med & Hyg* 1947, Aug, v 50 No 8, 159-60

The author has found the type form of *Anopheles rufipes* infected at Kano, N Nigeria, and states that previous dissections of small numbers had always been negative. Larvae were found only in large, sunlit, stagnant pools with clean water and upright, grassy vegetation, often along with *A. funestus* but never with *A. gambiae*

A. rufipes may be found in human habitations at the end of the rainy season in N Nigeria, but in relatively small numbers only. *A. funestus* especially, and *A. gambiae*, are much more numerous. Its importance as a vector of malaria is probably slight

Charles Wilcocks

RAO, V V On Gonotrophic Discordance among certain Indian *Anopheles*. *Indian J Malariology* 1947, Mar, v 1, No 1, 43-50 [11 refs]

The author describes some preliminary work on *Anopheles annularis* and *A. culicifacies* to show that while in the autumn there is a certain amount of gonotrophic dissociation, there is no general suspension of sexual activity in any species *en masse*, but that some individuals among the Indian anophelines enter into a condition midway between gonotrophic dissociation and gonotrophic concordance. In a mosquito in this state, which he calls gonotrophic discordance, the development of the ovaries does not keep pace with the nutrition but is dependent on repeated feeding. Full ovarian development may only be completed after a prolonged period, and during this time the female feels no urge to leave its feeding place to lay eggs. The author therefore puts forward the hypothesis that, as repeated feeding would appear to increase the chances of

infection, it is the mosquitoes with suspended or delayed sexual activity which may alone be responsible for malaria transmission while the majority which remain sexually active, do not as a rule transmit the disease, but help to keep up the population.

The author is unable to pursue the matter further but hopes it will be investigated by other workers.

H S Leston

WHITE R. Senior. On the Anthrophophilic Indices of some *Anopheles* found in East Central India. *Indian J. Malariology* 1947 Mar v 1 No. 1 111-22. [21 refs.]

The results are tabulated of some thousands of precipitin tests on the stomach contents of sixteen species of *Anopheles* captured in East Central India. In the case of five of these species (*Anopheles culicifacies*, *fluviatilis*, *versus*, *minimus*, and *aureolaris*) the results of dissections are also given in order that the infection rate may be compared with the anthrophilic index. The figures are presented under three heads—houses, cattle-sheds and out-of-doors. The author suggests that the differences observed in trophisms and in vectorial capacity point to the existence of biological races among these species, though only in the case of *A. versus* has any evidence been recorded (egg measurements) which might support this view—these measurements are awaiting statistical analysis.

The information regarding the remaining eleven species is much less complete and no infection rates are given for comparison.

FERNÁNDEZ MELÁNDEZ, A. Aportación al estudio del *Anopheles vestitipennis* en Cuba. [A Study of *Anopheles vestitipennis* in Cuba.] *Tijerkrans sobre Malaria*. Venezuela. 1946 Sept. v 10 No. 3, 133-6.

In Cuba, *A. vestitipennis* may be regarded as a much more important vector of malaria than was hitherto locally believed.

It shows a marked preference for feeding on human blood. *A. albimanus* shows no preference between human and animal blood, while *A. crucians* and *A. grahami* possess definite zoophilic characteristics.

Dissections of the stomachs and salivary glands of *A. vestitipennis* gave negative results, indicating that malaria transmission by the species was not active during the course of these investigations.

BOTD M. F. A Review of Studies on Immunity to Vivax Malaria. *J. National Malaria Soc.* 1947 Mar v 6, No. 1 12-31 13 figs. [10 refs.]

In this address, the author brings together the important observations made by him and his co-workers on immunity to *P. vivax* infections during a prolonged experience of malaria therapy. A clinical attack of three weeks or longer after inoculation with *P. vivax* indicates that the patient was previously completely susceptible. Short attacks from one day to two weeks may follow either heterologous or homologous reinoculation, indicating in the latter case, that immunity is incomplete. Homologous reinoculation may be followed by no clinical attack or fail altogether—the latter indicates a very effective refractory condition. A comparison of the parasit density at the beginning and the end of the clinical attack shows that a tolerance to the presence of the

parasites is the first manifestation of developing immunity. Soon after the infection becomes latent, the host is able to destroy numbers of parasites enormously greater than the few which can initiate an infection in a susceptible person. This destructive mechanism does not seem to be operative against sporozoites, but the resulting trophozoites will quickly disappear. The state of complete refractoriness may be of considerable duration, there is no evidence that its persistence is dependent upon the persistence of latent infection. The failure of serum of hyperimmune persons to confer passive immunity on susceptible persons indicates that the immunity is not humoral.

The possibility of conferring active immunity by inoculation with killed parasites is difficult to determine. Two susceptible patients saturated with quinacrine, were each given three inoculations of living parasites, which were presumably killed *in vivo*. Subsequent reinoculation by infected mosquitoes was followed by only a short clinical attack in each case. *Norman White*

WHORTON, C M, KIRSCHBAUM, W R., PULLMAN, T N, JONES, R, Jr, CRAIGE, B, Jr, ALVING, A S, EICHELBERGER, Lillian & COULSTON, F
The Chesson Strain of *Plasmodium vivax* Malaria I. Factors influencing the Incubation Period *J Infect Dis* 1947, May-June, v 80, No 3, 223-7
 [15 refs]

The Chesson strain of *P vivax* is of New Guinea origin. The observations recorded concerned psychotic patients in a hospital, and volunteer inmates of a penitentiary. Of 121 individuals receiving trophozoite infections, heparinized whole blood, 66 were inoculated with compatible blood, 55 with incompatible blood. The mean incubation period of the former group was 2.1 days, of the latter group 4.8 days. "Inoculation fever" is in most instances related to blood incompatibility. The incubation period varied inversely with the number of parasites in the inoculum.

In mosquito-induced infections there was a negative correlation between the approximate number of sporozoites injected and the length of the prepatent period. Three subjects who were bitten by from 45 to 80 heavily infected mosquitoes had prepatent periods of 9, 11 and 12 days as compared with the mean prepatent period of 13.6 days in 139 individuals each of whom was infected by the bites of 10 infected mosquitoes. *Norman White*

CRAIGE, B, Jr, ALVING, A S, JONES, R, Jr, WHORTON, C M, PULLMAN, T N & EICHELBERGER, Lillian. **The Chesson Strain of *Plasmodium vivax* Malaria II Relationship between Prepatent Period, Latent Period and Relapse Rate** *J Infect Dis* 1947, May-June, v 80, No 3, 228-36, 5 figs

These observations were carried out in a non-endemic area, only presumably susceptible white males were involved, and observations were restricted to primary attacks and first or second relapses, which were promptly treated by a variety of drugs.

In persons infected with the Chesson strain of *P vivax*, by the bites of 10 infected mosquitoes, the relapse rate was high when the prepatent period was short. Persons with a prepatent period of 14 days or less had a relapse rate of 96 per cent after treatment of the primary attack. When the prepatent period was 15 days or more the relapse rate was 58 per cent. One hundred and eleven cases were studied. The relapse rate after treatment of the first relapse was 85 per cent in patients who had had a short prepatent period, and 37 per cent in those who had long prepatent periods (82 cases observed).

The duration of the first latent period after treatment of the primary attack was usually short if the prepatent period had been short, 89 per cent of such

patients relapsed within 30 days, whereas only 48 per cent. of the relapses that occurred after long prepatent periods did so within that 30 days.

When the preceding latent period was under 30 days the relapse rate after treatment of the attack was 88 per cent. whereas it was only 52 per cent. when the latent period had exceeded that period (109 observations). The length of succeeding latent periods was positively correlated to the length of preceding latent periods.

The 30-day dividing line is not applicable to patients who have been treated previously with atabrin or with other drugs that persist in the body.

The relative importance of virulence and immunity as factors determining the severity of infections cannot be evaluated in such studies as these. The number of sporozoites injected is an important factor. If this be very high, the prepatent period is usually short.

WHORTON, C. M., YOUNT, E., JR., JONES, R. JR., ALVING, A. S., PULLMAN, T. N., CRADCK, B. JR., & ESCHELBERGER, Lillian. The Chesson Strain of *Plasmodium vivax* Malaria. III. Clinical Aspects. *J. Infect. Dis.* 1947 May-June, v. 80 No. 3 237-49 8 figs. [23 refs.]

This is a note of the clinical aspects of 195 sporozoite-induced and 123 trophozoite-induced cases of *P. vivax* malaria, Chesson strain. There were very few prodromata. Irregular remittent fever was observed during the first few days in both types of infection. In sporozoite infections, 80 per cent. of patients with primary attacks had quotidian fever; the incidence of quotidian fever was lower in relapses. In trophozoite-induced infections early quotidian paroxysms usually changed to tertian as the disease progressed. Chills were not usually experienced during initial remittent fever. In general the signs and symptoms appear to have differed little, if at all, from those generally seen in *P. vivax* malaria.

COOPER, W. C., COATNEY, G. R. & RUNK, D. S. Studies in Human Malaria. V. Homologous Strain Superinfection during Latency in Subjects with Sporozoite-Induced *Vivax* Malaria (St. Elizabeth Strain). *Amer. J. Hyg.* 1947 July, v. 48 No. 1 141-8, 1 fig. [20 refs.]

Fifty million homologous-strain *P. vivax* parasites were injected intravenously into 15 patients, 4 months after their original infection with mosquitoes. The long-term latency in ten of these patients had resulted from complete suppression of early attacks by quinine (mepracrine) or NIH 204 (SN 1796). In the other five patients latency followed treatment of early attacks. All the recipients except one developed prompt and severe attacks of malaria as the result of this superinfection. Neither by prepatent periods, incubation periods, densities of parasitaemia at onset of fever, rates of increase of parasitaemia, peak parasite densities, fever peaks nor responses to therapy could any consistent difference be found between the quinine group, the NIH 204 group, the otherwise treated group or in two patients who had experienced no prior sporozoite-induced infection. The one failure to secure a definite superinfection was in a patient who exhibited persistent patent parasitaemia after an inadequately treated early relapse. Treatment of all superinfections was begun on the 11th day after inoculation. The patients who developed superinfections later developed delayed attacks apparently resulting from the original sporozoite infections. These late attacks were contemporaneous with those of fifteen other patients who had received sporozoite infections at the same time but had not had superinfections.

Norman White

Ross, P Sub-Tertian (Malignant Tertian) Malaria in Europeans *East African Med J* 1947, Aug, v 24, No 8, 278-88

The author has over 20 years' experience in treating subtertian malaria amongst Europeans in Kenya. Most of his service has been in the Kisumu and Mombasa districts, and he has treated over one-thousand patients in hospital and several thousands as out-patients.

He considers that the "protean" nature of subtertian malaria has been greatly exaggerated and that an acute attack is a clear-cut entity and is comparatively easily diagnosed. In a patient coming from a malarious district, having a temperature, where no antimalarial drug has been given, competent examination of the blood repeated at intervals of 12 to 24 hours will prove the presence or absence of the disease almost invariably. If such drug has been given, two courses are open: either the drug is continued in full doses for a week—failure to respond being almost certain evidence that the condition is not malaria—or it is stopped and repeated blood examinations are made (the ideal course). [This of course is safe only when the patient is under close observation.]

It is not believed that, under proper observation, harm ever results from delaying treatment, except in children. The author has never seen a case of coma or convulsions with a negative blood slide. The habit of necessarily ascribing all of a patient's symptoms to a subtertian infection found in the blood is a bad one, and moreover textbooks do not sufficiently discriminate in their descriptions of the disease as it affects Europeans, Asians and Africans. In Europeans, dysenteric symptoms due to malaria are thought to be very rare, and even if parasites are found, the stools should be carefully examined in such cases. [Malaria and amoebic dysentery not infrequently co-exist in certain districts.]

The author has found that the disease rarely simulates appendicitis, although he has met with a proved case in which an appendix abscess subsequently developed. Chronic subtertian malaria is considered usually to be the result of repeated reinfections and is met with in Europeans living in an area so malarious that reinfections are unavoidable. Such patients treat themselves with quinine or mepacrine (usually in quite inadequate doses and irregularly), get into a state of "uneasy equilibrium" and are prone to blackwater fever.

Finally, the ultimate diagnosis of malaria rests with the microscope.

The newcomer is advised that particular note should be taken of the district from which the patient comes. [Very sound advice in East Africa.]

Areas are divided into Group I, townships such as Kisumu and Mombasa, where residents are liable to occasional infections only, and Group II, hyper-endemic areas where repeated reinfections are liable to take place. Care should be taken in ascribing unusual symptoms to malaria.

Subtertian malaria has very little tendency to relapse if it is properly treated, so-called relapses being nearly always due to reinfections. When malaria does relapse after the patient has left the endemic area the probability is, as the author points out, that there is a coincident benign or quartan infection.

All will admit that a great change has occurred in the therapeutics of malaria in the last 20 years. In the past, undoubtedly, too long and heavy courses of quinine were recommended, probably because relapse and reinfection were confused. The author has found that a course of 15 to 20 grains of quinine a day for 5 days and then 10 grains daily for a week, or of mepacrine 0.3 gm daily for 5 to 7 days, followed by a similar course for a week, is quite sufficient. His own last attack in 1942 was treated with only 80 grains of quinine and there was no suggestion of a relapse.

In a series of cases where quinine and mepacrine were given to alternate patients little difference in results was found but it was noted that the latter was rather slower in its action and that parasites disappeared more slowly from the peripheral blood. Two cases of psychosis were noted after ordinary doses of mepacrine and it is thought that the larger doses now sometimes recommended are unwise no benefit was found from giving the two drugs together and no treatment brought about disappearance of symptoms in less than 5 days in first attacks. Paludrine was not tried.

In chronic (usually recurrent) malaria, failing removal from the endemic area, each attack should be treated as it arises and a suppressive dose of mepacrine given daily.

Cerebral malaria has been found to be rare in European adults having efficient treatment, although it has been seen. It occurred most commonly in Group 2 cases, who have become careless. Blackwater fever usually occurred in Group 2 cases it was never seen in a first attack and followed as a rule irregular taking of quinine and also mepacrine. In contrast to cerebral malaria, it not uncommonly supervened in patients in hospital under treatment.

For cerebral malaria, it is thought that 5 grain doses of quinine given intravenously and repeated is the best treatment, although mepacrine has been used. In blackwater no specific was found, and sodium luminal in large doses intramuscularly did not reduce the mortality.

Malaria is a much more dangerous illness in children, especially infants, and here it does tend to be more "protean" in character. Withholding treatment while awaiting the result of blood examination is not recommended and it is important to give quinine or mepacrine, preferably by injection, at once in any suspicious case. Cerebral symptoms may develop very quickly but the treatment of this complication is more satisfactory than in adults. In infants, the onset may be very insidious. [In the reviewer's experience this is especially true in breast fed infants.]

The author considers the term *malignant malaria* is a bad one and unjustified. An occasional attack of subtertian malaria, if properly treated, makes little difference to the patient's general health. [The term malignant is probably a relic of bygone days when mosquito control was almost nil, the condition often not recognized or badly treated, and repeated reinfections frequent. In these circumstances, it was a very fatal disease and blackwater was common for instance in the Gold Coast, where circa 1830 some 30 per cent. of new arrivals died in their first year mostly from malaria and black water.]

Although no one is probably absolutely immune to this infection some appear to have a higher resistance than others, although here the degree of personal anti-mosquito prophylaxis must be taken into account. Those leading the quiet life usually suffer less than those who are constantly out at night.

Those living under Group 1 conditions are not advised to take any drug prophylaxis, those under Group 2 to take a daily suppressive dose of mepacrine. Paludrine has not been tried by the author.

[This is such an excellent paper and so full of practical experience that the reviewer hesitates to make any criticisms. It is, however suggested that —

1. The author tends to underestimate the protean manifestations of malaria.
2. In many cases parasites are extremely hard to find within the first 2 to 3 days of illness.
3. Cerebral malaria does occur with a negative blood slide, even in adults.
4. Malaria tends to simulate the symptoms but not the physical signs of other diseases, e.g. pain in the right iliac fossa, vomiting, possibly tenderness, but no rigidity and no diminution of peristaltic sounds.]

C. F. Shelton

HERNBERG, C A **Myocardial Affection in Malaria Tertiana** *Acta Med Scandinavica* 1947, Nov 5, v 129, No 2, 132-41, 6 figs

In 1944, the author saw 9 cases of myocarditis among 596 people suffering from "malaria tertiana" [presumably benign tertian] In three of these, electrocardiographic changes were uncertain, in the other six, which are described in detail, such changes did occur in some degree and included a reversible lowering of the S-T lead and a negativity of the T-wave at times, the P-wave was changed

The patients were all men between 20 and 40 years three were farmers and one each was a stone-worker, a chauffeur and a sausage maker [and were thus all manual workers, for the most part in moderately heavy occupations] Malaria parasites [presumably *P vivax*] were found in the blood of each patient, on admission in 3 cases, and, in the others, on the 24th day, the 4th week and not "till a relapse occurred"

The nature of the myocardial lesion was manifested by the presence of praecordial oppression, tachycardia, changes in the heart sounds and an increased sedimentation rate In only one case did permanent cardiac damage and insufficiency ensue

The myocardial condition was seen, on an average, 43.5 days after the first attack of fever, and usually about a fortnight after the end of antimalarial treatment The pathology of the condition is discussed and it is suggested that it may have been caused by blocking of the capillaries by malarial elements No other cause was found the patients were previously healthy soldiers on active service

On the basis of the return to normal of the sedimentation rate, the disappearance of symptoms and stabilization of the Ecg, the active process in the heart appeared to occur over a period of 3-10 weeks

H J O'D Burke-Gaffney

CHEN, J H & WU, Y K **Transfusion Malaria and its Prevention by Quinine Therapy** *Chinese Med J Shanghai* 1946, Nov-Dec, v 64, Nos 11/12, 309-14

This report is based on 233 blood transfusions performed in the Chungking General Hospital The blood was given to the patients immediately after withdrawal from the donors It was difficult to get a reliable past history of malaria from these donors One hundred and thirteen patients were given transfusions without quinine prophylaxis Twenty-one developed malaria, 18 *P vivax*, 3 *P falciparum* Five of the 21 patients had a history of past malaria moreover the hospital is in an endemic malaria area

The second group of 120 patients were given quinine by mouth as soon as possible after the transfusions, 0.3 gm four times daily for from 5 to 7 days None of these patients developed malaria in hospital

The authors recommend the routine use of quinine after blood transfusions in an endemic area such as Chungking

Norman White

ROGERS, K B **Quartan Malaria transmitted by Blood-Transfusion Report of a Case** *Lancet* 1947, Nov 8, 688-9, 1 chart [16 refs]

It is recognized that malaria may be transmitted by blood transfusion and it has been suggested that persons who had lived in tropical or sub-tropical areas should not be used as donors if others can be found [this *Bulletin*, 1940 v 37, 362, 456] This question has become more obtrusive now that many ex-service persons are potential donors, and the author records a case which emphasizes the risk of using donors who have visited malarious areas, without having had clinical manifestations of the disease

A young primipara, who had never travelled outside the county of Durham, received an antepartum transfusion of blood on March 8th 1948: this consisted of 2 pints of homologous (A) blood which had been stored for 3 days. She was discharged without incident, and was delivered of a healthy full-term child on March 14th at the same hospital. Except for one day of pyrexia, her post-partum was normal and she went home on March 24th.

Seven or eight weeks after the transfusion, she felt run down, sweated freely at night and eventually entered the county post natal convalescent home on June 15th, with a cold. On 18th she had a slight rigor which was repeated on 19th, 22nd and 25th: between the rigors, she felt well. On 25th, typical quartan malaria parasites were found in her blood: by this time, the patient was pale and had an easily palpable spleen and liver.

Blood examination which was very full and is recorded in detail, revealed, *inter alia*, 3,600,000 red cells per cmm., 10.5 gm. Hb per 100 cc., and a blood sedimentation rate of 53 mm. in 1 hour (Wintrobe).

Agglutination tests and blood culture were negative. The patient was treated with quinine and mepracrine to which she responded rapidly: up to the age of 5 months the child has shown no evidence of malaria.

There were two blood donors concerned. One had been on a cruise and had landed at Algiers for a few hours: no parasites were found in her blood. The second donor was a ship's engineer who had been to Aden, Abadan and Basra for five months in 1939. He had never had malaria (but several members of the crew had 3-day malaria on the homeward voyage). On his return to Britain in the summer of 1939 he had bouts of feeling cold for short periods, and would go to bed for an hour during the day. He had not been out of England since and had no illness except flu during a local epidemic.

Examination of concentrated centrifuged blood from the second donor by the author's technique [this *Bulletin* 1946 v. 43: 362] revealed the presence of a definite male quartan gametocyte.

On July 4th, blood from both donors was injected into two patients with G.P.I. who belonged to blood-group A: no evidence of malaria has yet appeared in the patient who received blood from the first donor: the patient given the blood of the second donor developed malaria on August 5th. It is noted that although this donor was an active malaria carrier his blood-sedimentation rate was not raised.

The author discusses the incidence of malaria transmitted by blood transfusion and surveys the relevant literature. He notes that the malaria transmitted by donors who have been absent from malarious areas for many years are nearly all quartan infections, though he mentions two benign tertian cases in the literature in which the donors had carried parasites for 3 and 10 years. He points out with SMUTE [this *Bulletin* 1944 v. 41: 1002] that quartan malaria is often no less common than the other varieties, and that it may be latent in persons from the tropics who act as donors. LÖNNER and NEWBOUSER [ibid., 91] have, however, shown that, when plasma is used, the risk of transmission of malaria is negligible: the author therefore suggests that persons who have been resident in malarious areas should not be bled for the production of whole blood for the purposes of transfusion.

H. J. O'D. Burke-Gaffney

WINCKEL, C. W. F. Quinine Injections in Malaria. *J. Trop. Med. & Hyg.* 1947 Oct. v. 50 No. 10: 201-3.

The author considers that quinine will still hold its place against the newer synthetic antimalarial remedies for a considerable time.

Parenteral administration of quinine is held to be justified only (1) When for some reason its oral use is impossible (2) to make sure that the drug is

actually being absorbed, (3) in very severe cases (e.g. cerebral malaria) when the quickest possible action is necessary.

In (1) and (2), intramuscular, and in (3) intravenous, injections should be given.

Until recently, quinine dihydrochloride was the compound of choice, but as the author points out, the acidity (pH 3.5) of the solution tended to cause pain and necrosis of tissue, the latter predisposing to infection and abscess formation even after the greatest aseptic precautions.

The author recommends the less soluble hydrochloride salt according to the following prescriptions (for intramuscular use) —

| | |
|-----------------------|---------------------|
| Quinine hydrochlor | 8 grains (0.5 gm) |
| Urethane | 4 grains (0.25 gm) |
| Aq. dest. ad | 1 ml |
| or Quinine hydrochlor | 4 grains (0.25 gm) |
| Antipyrin | 2 grains (0.125 gm) |
| Aq. dest. ad | 1 ml |

These solutions are nearly neutral and pain and necrosis are reduced to a minimum. The pH of these solutions may be raised to that of the tissues (pH 7.2) by adding a small amount of quinine base, this being the method used in the preparation of the German compound "Solvochin".

The following prescription gives a solution very nearly approaching the alkalinity of the body tissues

| | |
|---------------------------|------------------|
| Quinine hydrochlor | 45 grains (3 gm) |
| Antipyrin | 30 grains (2 gm) |
| Sol. hydratis sodi norm | 0.75 ml |
| Double-distilled water to | 10.0 ml |

This is for intramuscular injection only. It may be diluted up to three times its original volume without causing precipitation of quinine, it is not suitable for intravenous use. [No indication is given of the single dosage of this prescription which should be used.]

For intravenous use, the first two prescriptions should be diluted ten times and not more than 8 grains given at one time. Injections must be given slowly, one-tenth of the dose every minute. [The use of quinine hydrochloride might with advantage be tried out more extensively, especially for intramuscular injection. The advantages are that the injections are painless, necrosis of tissues is insignificant and therefore danger of sepsis is greatly reduced.]

C. F. Shelton

1. WINCKEL, C. W. F. The Malaria Patient and Quinine. *J. Trop. Med. & Hyg.* 1947, Nov., v. 50, No. 11, 219-20.
2. J. TROP. MED. & HYG. 1947, Nov., v. 50, No. 11, 211-12. The Route and Dosage in Antimalarial Therapy.

The author doubts whether mepacrine, paludrine and chloroquine can yet be issued wholesale with safety to the populations of tropical malarious countries in the same way in which quinine has been sold and distributed by various governments.

It is remarked that British and American authorities have tended to recommend larger daily doses of quinine than continental ones. The former generally advocate a daily dose of 30 grains or so. Thus MAEGRAITH (*Practitioner*, 1946, v. 157-81) recommends 30 grains a day for two days, followed by 20 grains daily for the next five, relapsed cases are treated with 30 grains combined with 30 mgm. pamaquin, daily for ten days, the quinine is given either as a

solution of bisulphate or as tablets of the hydrochloride or bihydrochloride. The author notes that the bisulphate contains 59 per cent. of quinine base, the hydrochloride and bihydrochloride 82 per cent.

P. falciparum infections may require more quinine than those due to *P. vivax* first attacks need larger doses than relapses, and a large discrepancy may exist on account of varying strains of plasmodia.

In the Netherlands East Indies, including parts of New Guinea, a daily dose of 22 grains of bisulphate or hydrochloride was found sufficient even for bad cases of *P. falciparum* infection, and in treating *P. vivax* a dosage of 15 grains was seldom exceeded. In 1832 in Java, Lichtenstein found that 9 grams daily of hydrochloride acted as well as 18 grams.

In Holland, the following treatment of *P. vivax* infections has been found successful—12 to 14 grains of quinine sulphate plus 45 to 54 mgm. pamaquin naphthoate (equal to about 30 mgm. pamaquin) are taken daily in 3 or 6 equal doses for 10 to 14 days. The author's point is that a small amount of quinine appears to be effective and there appears to be no reason why moderate doses of this drug should not work as efficiently in other parts of the world as in Holland and the East Indies.

[The reviewer believes it to be now generally held that excessive and too prolonged dosage with quinine is unnecessary and may be harmful—*our* experiences in Macedonia in 1917-18, when enormous doses of the drug were often given to malaria patients.]

ii. Two opposing views are put briefly in an editorial in the same *Journal*

(1) The surest way of obtaining the full action of quinine is by intramuscular injection, and this should be the routine in treatment of malaria.

(2) Intramuscular injection is unnecessary and dangerous and little short of malpraxis.

The view expressed in the editorial is that the parenteral route is seldom necessary and when it is, intravenous quinine is preferable to intramuscular but if the former is contraindicated the latter route may be used.

As pointed out by WINCKEL [above] the neutral hydrochloride salt is preferable to the highly acid and irritating bihydrochloride. The low solubility of the former may be overcome by addition of urethane and the resulting solution is nearly painless and non-irritating on intramuscular injection.

The danger of intravenous atabrin (mepacrine) is thought to have been exaggerated, but intramuscular injection seems to be just as effective, and the same applies to the newer synthetic drugs. As pointed out above there is a marked difference in the quinine base content of the various salts of quinine. During the recent war there has been a tendency to re-introduce the prescribing of larger doses of quinine, one possible reason being that the amount prescribed was not actually being taken.

Investigations with the synthetic antimalarial drugs led to the practice of loading the first few doses so as to reach the necessary blood concentration in the shortest possible time, but with quinine this is not necessary. The writer of the editorial under review is uncertain whether the minimal doses of quinine recommended by Winckel will be generally adopted.

[The evil reputation of intramuscular quinine in the past has probably arisen from the experience of those working in parts of the world where *C. leish* and other spore-bearing organisms are exceedingly common. Autoclaved sealed ampoules of quinine as supplied by any reliable firm of wholesale chemists are practically always sterile but difficulty may arise in the sterilization of needles and syringes, and the most careful precautions should be taken in this connexion.]

C. F. Skellern

GHOSH, B N & GHOSH, T K **Chemotherapy of Malaria with special reference to Paludrine.** *J Indian Med Ass* 1947, May, v. 16, No 8, 267-9

The authors discuss briefly the morbidity of malaria, the common anti-malarial drugs and the introduction of Paludrine they then give a brief [but not very clearly stated] description of the biology of malaria parasites and the conceptions of the exo erythrocytic phases, together with their therapeutic implications

The authors then report the use of paludrine by them in 50 cases of malaria, which could be followed up and supervised for a prolonged period Their results are summarized as follows —

| Average daily dose | Total dose for the course | Day of disappearance of fever | Day of disappearance of parasite | Relapse checked with periodic use |
|--------------------|---------------------------|-------------------------------|----------------------------------|-----------------------------------|
| 100 mg to 200 mg | 300 mg to 700 mg | 2nd day (90 per cent) | 2nd/3rd day (80 per cent) | 90 per cent |

It is stated that the drug is generally given in tablets of 100 mgm twice a day for two or three days until the fever subsides except for slight nausea, "which is not felt when taken with a glass of water", no toxic symptoms were observed, no untoward effect was observed when the drug was used in the case of two pregnant women

"In malignant malaria it will cause definite cure But relapses may occur in benign tertian after a few days when it may be used twice a week for 3-6 months to stop it

The authors discuss the estimated quinine needs of India and compare them with the economic advantages of paludrine They finally draw a number of conclusions regarding paludrine which accord in general with those of many other observers but these conclusions do not all follow from the somewhat scanty experimental records provided in the paper [The authors do not give details of their cases or the types of malaria of which they consisted conclusions regarding prophylaxis and suppression are drawn without provision of experimental evidence on which to support them See also this *Bulletin*, 1948, v 45, 34-6]

COOPER, W C & COATNEY, G R **Studies in Human Malaria III The Therapeutic Effect of a Phenanthrene Amino Alcohol, NIH-204 (SN-1796), in Vivax, Falciparum, and Quartan Malaria** *Amer J Hyg* 1947, July, v 46 No 1, 119-31 2 figs

The chemical formula of NIH-204 is 9-(2-diamylamino-1-hydroxyethyl)-1, 2, 3 4-tetrahydrophenanthrene hydrochloride This report summarizes the treatment of 66 malaria attacks in 47 patients undergoing therapeutic malaria in a mental hospital Fifty-one attacks were due to *P vivax* In these infections 0.5 gm of NIH-204 or more a day for 6 days relieved the clinical attack and reduced parasitaemia to subpatent levels in all but one instance Relapses occurred after treatment of all sporozoite-induced early attacks, regardless of dosage Prompt relapses (4 to 27 days after treatment) appeared after all early attacks treated with 0.25 gm daily and in the majority treated with 0.5 gm daily but after only 3 of 16 attacks treated with 0.9 gm daily relapses in the 13 other cases were delayed 153 to 273 days Thirteen attacks due to *P falciparum* were treated with NIH-204 The doses were 0.96 gm daily in 10 cases, 1.5 gm daily in 3 cases In all but one

instance there was parasite and clinical response. The clearance of parasites and subsidence of fever were generally slow in primary attacks. Early relapses occurred after 5 of the 6 primary attacks and after 2 of 4 first relapses.

Two blood-induced *P. malariae* infections were treated with NIH-204; parasites disappeared and fever subsided in both. There was no relapse during 4 years of observation.

Symptoms of intolerance noted were lowering of the threshold of pilomotor stimulation in most cases, marked but asymptomatic bradycardia in 42 cases, difficulty in passing urine in 8 cases, and microscopic haematuria in 17.

At the doses used, which were near the limit of tolerance, NIH 20 is certainly no better than quinine and definitely inferior to mepracrine in the treatment of *P. falciparum*. It is inferior to both drugs in the treatment of *P. falciparum* infections.

DECOURT P. & SCHNEIDER, J. Traitement curatif du paludisme par divers sels du 3-méthyl-4 (diéthylaminopentyl) amino-7-chloroquinoline (nivaquine) [Curative Treatment of Malaria with various Salts of 3-Methyl-4 (Diethylaminopentyl) Amino-7-Chloroquinoline (Nivaquine)] *Bull. Soc. Path. Exot.* 1947 v 40 Nos. 1/2, 14-17

Three salts of nivaquine the composition of which is indicated in the title to this paper have been tested in the treatment of malaria in Tunisia: a methylene bis-oxynaphthoate, Nivaquine M; a resorcin-carbonate, Nivaquine R; a dichlorhydrate Nivaquine C. Nivaquine was formerly known as Sontoquine.

More than 150 patients have been treated with Nivaquine M. The average dose was 0.6 gm. a day for 5 days. Fever was controlled in 36 hours and schizonts disappeared from the peripheral blood in 48 hours.

Nivaquine R was used in the treatment of only 17 patients. The results were very much less favourable than those obtained with Nivaquine M.

Nivaquine C was much more active in the treatment of malaria than either of the two other preparations. More than 200 patients have been treated with it. The daily dose in cases of average severity was 0.3 gm. A daily dose of as little as 0.08 gm. is sufficient to arrest the attack. 0.1 gm. of quinine is necessary to secure the same result. Patients treated for 5 to 7 days are always apyretic at the end of 36 hours: no relapses were noted in the several weeks during which the patients were under observation. All doses in this paper are doses of base.

DE MEILLON B & THORP, J M The Inhibition of Growth of Larvae of *Aedes aegypti* by certain Anti-Malarial Drugs *South African J Med Sci* 1947, Jan, v 12, No 1, 33-8

In this paper are recorded the results of experiments which demonstrate the inhibition of the growth of the larvae of *Aedes aegypti* by quinine and atabrin [mepacrine] and the reversal of this inhibition by dietary means. This work has followed on that of MADINAVEITIA [this *Bulletin*, 1946, v 43, 1011], who found that antimalarial drugs inhibit the growth of *Lactobacillus casei*, and HELLERMAN *et al* [*ibid*, 1947, v 44, 400], who showed that adenylic acid could reverse the inhibitory effect of quinacrine on the growth of *Plasmodium lophurae*. The object of this paper was to examine the relation of these effects of antimalarials to living systems other than micro-organisms.

In an adequate medium containing minimal quantities of brewer's yeast and a vitamin mixture, reversal of inhibition was attained by increasing the yeast fivefold or by the addition of the water-soluble fraction of yeast, definite reversal did not follow an increase in concentration of the vitamin content, namely thiamin chloride, riboflavin, pyridoxin, pantothenic acid and nicotinic acid.

GOLDBERG L & DE MEILLON B Further Observations on the Nutritional Requirements of the Larva of *Aedes aegypti* L *Nature* 1947 Oct 25, 582-3, 1 fig [See also DE MEILLON & THORP above Detailed findings will be furnished later]

PACKER, H Experimental Field-Type Suppression with SN 7618 (Chloroquine), SN 8137 and SN 12,837 (Paludrine) *J National Malaria Soc* 1947 June v 6, No 2, 147-54

These observations were carried out on white neurosyphilitic patients, without a previous history of malaria, who had been admitted to hospital for malaria-therapy. The McCoy strain of *P vivax* and the Costa strain of *P falciparum* were used, and insectary-bred *A quadrimaculatus* was the vector.

Twelve patients received weekly doses of SN 8137, from 0.125 to 0.5 gm. without a priming dose. They were given mosquito inoculations of *P vivax* on three alternate days of the first week, the first weekly dose of drug being given the day before the first inoculation. The weekly dose of drug was continued during three consecutive weeks following the week of inoculations. The minimum effective weekly suppressive dose was found to be between 0.125 and 0.25 gm. No break-through occurred when the higher dose was given.

Equivalent doses of SN 7618 (chloroquine) were not so effective against *P vivax* break-throughs occurred with 0.25 gm weekly. If, however, a priming dose of double the weekly maintenance dose was given a week before the week of inoculations the results obtained were similar to those obtained with SN 8137. The minimum effective dose of paludrine against *P vivax* was not determined but observations on four patients showed that the amount of the drug required against *P falciparum* paludrine was found to exercise suppressive action comparable with that of chloroquine in doses three times as large. *P falciparum* infections require higher doses of either drug for effective suppression than do *P vivax* infections.

Paludrine given on any day between the first and fifth days, inclusive, after *P falciparum* mosquito inoculation gives protection. If given on the sixth or seventh days infection breaks through. This confirms Fairley's observation

that palabrine is a true causal prophylactic in *P. falciparum* malaria and is more active against pre-erythrocytic forms than against the erythrocytic stages of the parasite.

- i. COATNEY G. R., COOPER, W. C., YOUNG M. D. & McLENDON S. B. *Studies in Human Malaria. I. The Protective Action of Sulfadiazine and Sulfapyrazine against Sporozoite-Induced Falciparum Malaria.* *Amer J Hyg* 1947 July v 48 No. 1 84-104. [17 refs.]
- ii. — — — BURGESS, R. W. & SMARR, R. G. *II. The Suppressive Action of Sulfadiazine and Sulfapyrazine against Sporozoite-Induced Vivax Malaria (St. Elizabeth Strain)* *Ibid.* 105-18 1 fig. [29 refs.]
- iii. — — — & — — — *IV. The Suppressive Action of a Phenanthrene Amino Alcohol, NIH-204 (SN 1796) against Sporozoite-Induced Vivax Malaria (St. Elizabeth Strain).* *Ibid.* 132-40 2 figs.

i. I—These investigations were carried out in 1942-43. For the *P. falciparum* investigation, the subjects were selected from white and Negro male patients in two large mental hospitals. The McLendon strain of *P. falciparum* was used. This was isolated from a patient in South Carolina in 1940. Insectary-reared *A. quadrimaculatus* were used as vectors. Sulphadiazine and sulphapyrazine were given in 0.5 gm. tablets. In all but one test administration of the drug was begun before exposure to infection. The tests involved 75 treated and 36 control subjects. Sulphadiazine in doses of 12 gm. a day continued for 48 hours after exposure with blood concentrations over 20 mgm. per 100 ml. did not act as a causal prophylactic of *P. falciparum* malaria: the prepatent and incubation periods were, however, doubled. Four grammes daily for 6 days after exposure, or 2 gm. daily for 5 days or 10 days, produced delay of patent infection. Four grammes daily for 11 days after exposure prevented infection in 4 of 5 patients. Four grammes daily for 42 days after exposure protected all of 10 patients. 2 gm. daily for the same period 9 out of 10. 1 gm. daily for the same period protected 8 out of 9. 0.5 gm. daily for the same period prevented patent parasitaemia and clinical attacks in 3 of 5 subjects, but borderline clinical symptoms occurred. The minimum blood concentration of sulphadiazine associated with suppression was approximately 1.1 mgm. per 100 ml.

One-half gramme of sulphapyrazine daily for 42 days after exposure gave results similar to those given by the same dose of sulphadiazine.

As a suppressive of *P. falciparum* malaria sulphadiazine possesses no advantages over atebcin (mepacrine).

ii. II—Similar observations were carried out on white male patients infected with the St. Elizabeth strain of *P. vivax*. Sulphadiazine 3 gm. daily for 2 days before and 42 days after infective mosquito bites, did not prevent infection in any of 10 patients. Mean minimum blood concentrations of over 5.0 mgm. per 100 ml. were suppressive: in 4 patients, malaria appeared 9 to 11 months after infection. With smaller doses the majority of patients developed clinical attacks while receiving treatment. Sulphapyrazine, in daily doses of 1.0 and 0.5 gm., was similarly ineffective. With these drugs, *P. vivax* malaria is far more difficult to suppress or prevent than is *P. falciparum* malaria. Both drugs are poor suppressants of the strain of *P. vivax* used, compared with either quinine or mepacrine.

iii. IV In this study 30 white patients were observed. The suppressive action of NIH 204 (SN 1796)—a phenanthrene amino-alcohol—was compared with that of mepacrine against *P. vivax* infection. There were ten patients in each of the two groups and ten controls who received no protective medication. NIH 204 was given in capsules containing 0.15 gm. of the hydrochloride.

(91.2 per cent base) Quinacrine [mepacrine] dihydrochloride was given in standard 0.1 gm tablets. Each man was bitten by from 3 to 7 infected mosquitoes on each of 3 days spaced evenly over a week. NIH-204 0.3 gm daily, for 2 days before, 7 days during, and 28 days after the week of infection, effectively suppressed *P. vivax* malaria, as did quinacrine hydrochloride 0.1 gm daily commencing 8 days before the week of infection. All of the subjects developed delayed primary attacks 6 to 10 months after exposure to infection. NIH-204 is not recommended for the field suppression of malaria because of annoying side-actions that accompany its use, and because better suppressants are available. The side-actions were lowering of the threshold of pilomotor stimulation, slowing of the pulse, difficulty in urination, and microscopic haematuria.

MISSIROLI, A. Riduzione o eradicazione degli anofeli? [Reduction or Eradication of Anophelines?] *Riv di Parassit* Rome 1947, June-Sept, v 8, Nos 2/3, 141-69, 9 figs. English summary (7 lines) Norman White

In the autumn of 1943 there were large inundations of parts of the Tyrrhenian seaboard of Italy owing to the war. Breeding of mosquitoes increased and, in addition, the percentages of *Anopheles maculipennis labranchiae* rose to nearly 100 per cent in some areas. The result was a great increase in the incidence of malaria. A new method of attack on this old problem was attempted with the aid of funds and equipment from UNRRA and other sources. Instead of anti-larval treatments and other measures, reliance was placed on anti-adult spray-painting of houses and animal sheds with DDT. The method has proved so successful that a five-year plan has been started to eradicate malaria from Italy. The country falls into four distinct regions differing in their particular malaria problems. (I) The northern plain of Lombardy has only local patches of malaria, due to *Anopheles maculipennis atroparvus*. (II) The coastal region of the northern end of the Adriatic has malaria spread by *A. sacharovi*. (III) The central part of Italy suffers from malaria spread by *A. m. labranchiae* which occurs along the coast of Tuscany and Lazio at places below 300 m above sea level. (IV) The southern part of Italy as well as Sicily and Sardinia constitute the most difficult problem, for malaria spread by *A. m. labranchiae* is common everywhere in regions below 1,000 m above sea level.

The aim of the plan is to treat all houses in the malarious patches of zones I, II and III in the first year, in the second year, to deal with the western and in the third year the eastern halves of zone IV. Results of work completed so far are given in graphs which show the monthly statistics for certain areas in 1945 (before DDT spraying) and in 1946 (afterwards). The graphs show striking declines in numbers of mosquitoes at catching stations, reported cases of malaria, positive blood films, deaths from malaria and also from all causes. The decline from all causes is due to the absence of a peak during the summer months in the year of DDT spraying. This appears to be due not so much to the effect on malaria as to a reduction of enteric diseases consequent on the widespread destruction of houseflies achieved by the DDT. Figures are also given of parasite rates and spleen indices for March 1946 and March 1947.

The author briefly discusses the possibility of eradication of mosquitoes and remarks that further judgment can be made at the end of an eradication campaign now in progress in Sardinia. He concludes that it would take fifteen years at least to do such a thing in Italy itself and would be exceedingly costly. On the other hand the use of DDT spray-painting was easier and cheaper and affected flies and other parasites as well as mosquitoes. An indication of a race

of flies with unusual resistance to DDT complicated the picture, but it appears that they may be attacked with other similar insecticides. J. R. Buxton

PUTNAM, P & HACKETT L. W. An Appraisal of Malaria Reduction in Albania, 1929-1938. J. National Malaria Soc. 1947 June, v 6 No 2, 131-46 7 figs.

Malarial surveys and antilarval measures were started in Albania in 1929 by the Health Department of that country under the auspices of the International Health Division of the Rockefeller Foundation. Antilarval schemes were carried out in Tirana, the capital, Durazzo, its port, two inland towns, Elbasan and Berat, and the coastal town Valona. Kavaja, a coastal town just south of Durazzo was used as a control area. Annual surveys of school children, from 5 to 12 years of age, were made in February or March in all these towns.

Anopheles sacheroi is the important vector of malaria in the coastal plains where it breeds in the salty lagoons. *A. maculipennis maculipennis* and *A. m. subalpinus* were found wherever collections were made. *A. m. messeae* is a highland species. *A. superpictus* was found breeding extensively in the gravel beds of torrents during the dry summer. *A. maculipennis (maculipennis and subalpinus)* could be captured throughout the year but the high peak of prevalence occurred in June and July. *A. sacheroi* was prevalent in May, June and July, the shortness of the season being due to the increased salinity of the breeding grounds in the dry season. The seasonal prevalence of *A. superpictus* was irregular. The prevalence curve showed two peaks each year but specimens could be captured in any month.

At Tirana, where *A. superpictus* is the chief vector swamps were drained and all the river water was diverted above the town into a well-regulated irrigation system throughout the breeding season. At Durazzo the salinity of the lagoons was increased by admitting sea water at high tide. At Elbasan and Berat palm green was used extensively. At Valona filling and draining of swamps and lagoons were commenced but progress was slow.

The reduction in malaria is appraised by statistical methods. A reduction occurred in each of the protected areas, greatest in Tirana and Durazzo where permanent measures were possible. In Tirana the density of *A. superpictus* dropped sharply from 1932 to 1938 while that of *A. maculipennis* remained constant. In Elbasan and Berat the density of both species decreased. In Valona there was no decrease either in *A. sacheroi* captures or in parasite rates.

I. AZIZ, M. Report on the Anopheles (Malaria) Eradication Scheme Karpas-Cyprus 1946. 67 pp. numerous graphs & charts & 33 figs. 1947. Nicosia Cyprus Govt. Printing Office.

11. — A Brief Account of the Anopheles (Malaria) Eradication in Karpas-Cyprus, 1946. J. Roy. Soc. Med. 1947 Sept., v 67 No. 5 488-500 3 figs.

i. The first stage of an attempt to eradicate anopheline mosquitoes and malaria from the island of Cyprus has been completed. The story is told in full in the first paper and summarized in the second.

The area chosen for the first season's work, 1st April to 16th November 1946 was the Karpas, the narrow tongue of land to the north-east of the island, the topography of which is described. It consists of about 450-500 square miles, but an additional inland protective area of some 250 square miles was also included and placed under control as a protection against anopheles infiltration. In the rest of the island, the usual routine control, limited to $1\frac{1}{2}$ miles around towns and villages, was continued. The population of both areas is 34,000.

living in 65 villages. The anophelines are *A. superpictus*, *claviger*, *sacharovii*, *algeriensis*, *martini* and *hyrcanus*, *A. multicolor* occurs in other parts of the island. The three first named are known to be vectors of malaria, *A. superpictus* being responsible for 95 per cent of the rural malaria. In the island there is an average of 10,500 cases per annum with 18,000 in some years.

The recruitment of staff, organization of the eradication scheme and the duties of each member are described. When complete, the staff consisted of an executive officer and his assistants, a district officer, 2 headquarters inspectors, 4 section officers, 1 malaria technician, 2 field inspectors, 8 zone officers, 1 store-keeper, 3 clerks and between 75 and 80 labourers. The relationship between the workers had to be understood by all the checking and counter-checking of each other's work formed an essential part of the scheme and had to be undertaken without bad feeling or suspicion. Those accustomed to ordinary control work had to become "eradication-minded" and had to be continually impressed with the necessity for negative reports. The many difficulties encountered, and how they were overcome, are described in some detail. For example it was not possible to continue with routine treatment of vehicles travelling through the area until the public health legislation had been amended, and by that time it was too late to be effective. Some of the staff deserted for less hazardous occupations, but this was counteracted to some extent by the issue of free clothing, boots, soap and so on.

The area was divided into 51 blocks of 10 to 30 square miles each, though the sizes had to be adjusted in the light of experience as the work progressed. In each block were 12 plots and one labourer was expected to do one plot per day. Blocks were grouped into 10 zones and the whole peninsula into 4 sections. Most attention was given to breeding places. These were dotted over many places. Some of them were very difficult to reach. At first, DDT residual spraying was not done but 'ordinary insecticide' was used in houses, stables, etc. as it was not possible to treat buildings properly because there were many rooms to which the operators were not admitted, later, a "light DDT spray" was used in adult resting places as the weather got colder.

The materials used were against larvae, 8,416 gallons of 4 to 5 per cent DDT in gas oil (fuel oil), against adults, 160 gallons of 3 per cent DDT in gas oil, 'ordinary insecticide' [pyrethrum] 168 gallons, 193 larvicide sprayers (lengthened fit guns) and 84 standard fit guns, all made locally. The cost to 31st October 1946 was £12,000. Monthly progress was recorded in tables and on maps until finally it was possible to show that no anopheline mosquitoes had been reported between 6th October and 16th November 1946.

The text occupies 14 foolscap pages but there are 40 pages of tables, charts, maps and samples of the forms used as well as 35 photographs. It was read before the Tropical Hygiene Section of the Health Congress of the Royal Sanitary Institute in June 1947.

A careful search of the 1946 eradication area has, up to 10th February 1947, revealed no adults and no larvae of *A. superpictus*. A few larvae of *A. claviger* and *A. martini* have been found in isolated waters. In this paper, the total cost of the scheme for 1946 is put at £18,000 which represents ten shillings per head of the population or £36 per square mile.

In the discussion following the paper it was pointed out that the work in Cyprus emphasized once again the fact that every malaria problem is a local one. This was illustrated by one point, that in the *superpictus* eradication work the fit type of sprayer suited the conditions in Cyprus and was the most economical, isolated patches of water could not be economically dealt with by the drop method as used in the Sudan. The author was unable to give figures for the amount of DDT used per acre, but the amount of larvicide used by one man per

day averaged about one gallon. Wells were treated with the same larvicide as surface water and it was also used to spray the sides of the wells to kill resting adults.

The campaign for 1947 is planned to take in half the island, and in preparation, a winter scheme is in progress consisting of an attack on adult harbourages with DDT in gas oil.

PURI, I. M. RAJINDAR PAL KRISHNASWAMI A. K. BHATIA, M. L.
Studies on some Insecticides against Anopheline Adults and Larvae. I. Preliminary Experiments at Delhi with DDT [PURI & RAJINDAR PAL]. *Indian J. Malariology* 1947 Mar v 1 No. 1 133-58, 7 graphs. [16 refs.]. II. DDT as Residual and Space Spray and as Larvicide [PURI & KRISHNASWAMI]. *Ibid* 159-81 28 graphs. III. Experiment with DDT as a Residual Spray in some Villages in Baluchistan [PURI & BHATIA]. *Ibid*. 183-91 3 graphs. IV. Experiments with DDT and 666 as Residual Spray in some Villages around Delhi in 1946 [PURI & KRISHNASWAMI]. *Ibid*. 193-209 7 graphs.

Staff of the Malaria Institute of India have conducted experiments to assess the potentialities of DDT as a mosquitocide and larvicide and to study methods of application under Indian conditions. Their results are largely confirmatory of the work of workers in other countries, but in publishing them they have performed a valuable service for field workers in India.

Part I Preliminary Experiments at Delhi with DDT

The materials used were mainly 5 per cent. DDT solution in kerosene, malanol or used engine oil and DDT turpentine emulsion the method of preparation is fully described. The results were as follows —

- Larvicide (a) DDT in oil was very effective in doses of 4 to 6 cc. per 10 sq. yards.
- (b) DDT turpentine emulsion is more effective than () thus 2 to 4 cc. of 5 per cent. emulsion (100 to 200 mgm. of DDT) per 10 sq. yds. gave 100 per cent. control for 5 to 8 days and partial control for 12 days.
- (c) Aerial spraying is wasteful and very erratic

Residual-Insecticide Both oil and emulsion produced, in mud huts, a 100 per cent. reduction in adult mosquitoes during the first four days, with a partial residual effect persisting for four to five weeks the dose was 150 mgm. to 200 mgm. per sq. foot.

Part II

1 DDT as Larvicide Nilgiris South India

Tabulated results show the effect of 5 per cent. DDT in a turpentine emulsion and in solution in kerosene, used engine oil and malanol, when applied to flowing streams, to still water in pits and to fallow or growing ricefields. In still water 0.6 cc. of solution per 10 sq. yds. as compared to 3 to 4 cc. in stream or ricefield, was sufficient to produce 100 per cent. kill. A residual effect for 6 to 8 days was evident in ricefields with doses of 2 to 5 cc. of 5 per cent. solution per 10 sq. yards. Higher aquatic fauna appeared to be unaffected.

2 DDT as an indoor residual spray Bengal Town

Graphs illustrate the effect on indoor anopheline populations of a single application of a 5 per cent. solution or emulsion at a dose of 1 quart per 1,000 sq. ft. of mud plaster surface. Results for solution or emulsion were similar at nearly 100 per cent. reduction for a number of days, the residual

toxicity lasting for two months, increased dosage did not lengthen this period
A. minimus was more sensitive to the residual action than other anophelines

3 *DDT as an outdoor residual spray* Bengal, Terai

Bushes, fences, lanes and the outer surfaces of walls and roofs of huts in a 50-yard belt surrounding groups of dwellings were sprayed with the various 5 per cent DDT solutions or emulsion. Results are depicted graphically and indicate that a dose of 1 to 3 gallons per acre caused an appreciable reduction in the indoor mosquito population for periods up to 13 days. *A. minimus* in particular reappeared later than other mosquitoes. Rainfall vitiated the residual action.

4 *DDT as a space spray* (5 per cent DDT-kerosene solution) Bengal, Terai
 This solution used in the interior of dwellings twice a week for three months resulted in a marked reduction of the sporozoite rate among *A. minimus*. As a malaria control measure this is as effective as the use of pyrethrum spray.

Part III

Quetta (Baluchistan) was selected for further experiments with DDT as a residual indoor spray, because it differed from previous areas of Papers I and II in having a short malaria and mosquito season, and in having *A. superpictus* as the main vector mosquito. A dose of 50 mgm per sq ft reduced the mosquito population to negligible numbers for 10 weeks. A dose of 25 mgm per sq ft though not producing a 100 per cent reduction in numbers of mosquitoes, did appear to reduce the sporozoite rate among *A. superpictus* present.

Part IV

Experiments were conducted in the Delhi area to compare the efficiency of DDT and Gammexane as residual insecticides. The authors, although making observations on the results with DDT, were not prepared to express an opinion on Gammexane because "the experimental conditions under which this test was carried out" did not permit it.

PURI, I M. The Practical Application of DDT for Malaria Control in Rural and Urban Areas in India. *Indian J. Malariology* 1947, Mar., v 1, No 1, 211-20.

This paper summarizes the previous four and has reference to costs which are of little assistance outside India.

R Ford Tredre

BRESCIA, F & WILSON I B. Treatment of Native Villages with the Aerosol Generator. *J. Ecomom. Entom.* 1947, June v 40, No 3, 313-16.

[The paper begins with the alarming phrase "Two villages were treated to determine whether an oil-DDT aerosol generated outside native huts can kill adults resting inside the huts during the course of treatment." It seems, however, that mosquito adults are implied.]

The villages were thatched native villages in the Solomon Islands. No details of the generator are given, but it is stated that it produces an aerosol with particles of 10-microns diameter. A dosage of 5 lb DDT per 1,000 feet of front was sufficient to destroy *Anopheles farauti* inside and outside the huts and to kill larvae but it only gave a protective period of five days in one village and one day in another. [The front is the distance covered by the generator carrier.] To obtain "an appreciable" protective period it is necessary to use 20 lb of DDT per 1,000 feet of front (the front extending 2,000 ft beyond the

village) if breeding occurs in pools over 1 000 feet from the village. Where breeding is restricted to pools less than 1,000 feet from the village, a dosage of 10 lb. DDT should suffice.

J. R. BROWN

HIDMAN E. H. & CUTKOMP L. K. Block Residual Spraying of Premises with DDT for the Control of Malaria. *Amer J Trop Med.* 1947 July v 17 No. 4 449-61 1 map.

As a result of the experimental work by HARRIS and KRAMER (this Bulletin 1947 v 44 880) in the Tennessee Valley the DDT residual spray technique has been applied to an area adjacent to the Wheeler Reservoir (Tennessee Valley Authority) in North Alabama (35°N 87°W) a neighbouring area being used for control purposes. The treated district contained 299 occupied premises in 38 sq. miles, compared with 238 in 33 sq. miles in the untreated control district. Approximately the same percentage of mosquito-proofed residences were present in the two districts.

The interiors of all types of structures (houses, barns, privies, animal habitations etc.) were treated with 5 per cent. emulsion of DDT (Stock solution 25 per cent. DDT 73 per cent. Xylene, 2 per cent. Triton) by means of knapsack sprayers rate of application approximated 200 mgm. of DDT per sq. foot costs, excluding supervision, were at the rate of 0.91 dollar per 1 000 sq. feet.

The reduction in numbers of the vector anopheline, *A. quadrimaculatus*, is evident in the following table.

Average number of *A. quadrimaculatus* mosquitoes per premise

| Area | Pre-Treatment Inspection | Post Treatment Inspections | | | | | | | | |
|---------|--------------------------|----------------------------|------|------|--------|------|------|-----------|------|------|
| | June | July | | | August | | | September | | |
| | | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 |
| Sprayed | 20-00 | 0-4 | 0-4 | 0-9 | 1 1 | 1 2 | 1 2 | 2 1 | 2 8 | 6-2 |
| Control | 23 3 | 32-9 | 32 1 | 35-6 | 43 8 | 31 1 | 13-1 | 15 1 | 29-4 | 14 2 |

The figures are based on the total numbers caught in all structures on premise.

Catches of adult mosquitoes in certain unsprayed sections of barns and in well-placed traps, and larval density surveys in adjacent breeding waters, showed that high production of mosquitoes continued despite the premise spraying.

Examination of thick blood films of 90 per cent. of the inhabitants of both districts was completely negative and no conclusion is possible on the effect of the spraying on malaria transmission.

As a result of this experiment and previous information on human blood-feeding of *A. quadrimaculatus* the authors are of opinion that DDT residual spraying of all structures offers more protection against malaria transmission than mosquito-proofing

R. Ford TREBBS

CUTKOMP L. K. Residual Sprays to control *Anopheles quadrimaculatus*. *J Econom. Entom.* 1947 June v 40 No. 3 328-33 3 figs.

The paper reports tests in the laboratory and in unoccupied houses, of various insecticides applied at rates of 100-250 mgm. per sq. ft. The toxicity at different

times was judged by the exposure period necessary to cause knockdown of *A. quadrimaculatus*, the experience of the author being that mosquitoes thus affected never recovered (except, sometimes, with pyrethrins)

The results showed pyrethrins and then gamma benzene hexachloride to be most toxic according to this criterion, followed by DDT and "Chlordane" ($C_{10}H_6Cl_8$) and, finally, "Toxaphene" ($C_{10}H_{10}Cl_8$). The residual action of DDT was greatest, followed by those of benzene hexachloride and "Toxaphene", which declined somewhat after fifteen weeks but, under some conditions, were still effective at the end of a year. Pyrethrins and "Chlordane" were least persistent.

An experiment was performed to compare the irritant effects of the various insecticides, calculating the percentages of mosquitoes leaving treated houses in which they were liberated. The figures observed were —

| Houses treated with— | (200 mgm /sq ft) | 80 per cent left the houses |
|----------------------|------------------|-----------------------------|
| Pyrethrins | 250 | 57 |
| DDT | 100 | 83 |
| Benzene hexachloride | 160 | 35 |
| Toxaphene | | " " |

DAVIDSON, G. Field Trials with "Gammexane" as a means of Malaria Control by Adult Mosquito Destruction in Sierra Leone I. The Effect of "Gammexane" on Mosquitoes. *Ann Trop Med & Parasit* 1947, Sept, v 41, No 2 178-209 2 maps, 2 text figs & 12 figs on 3 pls

The insecticidal properties of hexachlorocyclohexane (benzene hexachloride, $C_6H_6Cl_6$) were first noted in 1942 by Imperial Chemical Industries Ltd, and in 1943 the active insecticidal constituent, the gamma isomer, Gammexane, was isolated.

Various workers showed by laboratory experiment that Gammexane is lethal to mosquitoes in smaller concentrations than DDT, and is quicker in its action. This paper describes experiments conducted in Sierra Leone to measure the rue value of Gammexane for the destruction of adult *Anopheles gambu*.

Three groups of villages were selected

(a) A coastal group at the foot of the mountains on the open sea

(b) An inland group in the Protectorate associated with mining

(c) A single large village on the Freetown estuary

Smoke Generators containing Gammexane A trial of this method in four villages proved it to be inefficient mainly because of the impossibility of sealing the type of house

Residual Sprays containing Gammexane Detailed description is given of products used, machines for, and technique of spraying. The walls of houses had a variety of surfaces, wood mud thatch, concrete and corrugated iron

A detailed analysis of the results in each sprayed village and of the variations of mosquito density in the unsprayed control villages is given. These results may be summarized as follows —

- 1 Gammexane in the form of a residual spray is an efficient means of reducing the population of mosquitoes in houses
- 2 0.5 per cent solution applied at rate of 10 mgm per square foot (4 pints of solution or mixture to 1,000 sq ft) to every available internal wall surface of all houses will reduce the mosquito population in the houses to almost nil for a period of six months
- 3 Lowering of mosquito density in unsprayed houses in adjacent areas was noted

(1305)

4. In admittedly small numbers of dissections 247 from treated and 159 from untreated villages, the sporozoite rate was 2 per cent. in the former compared to 4.4 per cent. in the latter

R. Ford T. *cibv*

DAVIDSON G. Field Trials with "Gammaxane" as a means of Malaria Control by Adult Mosquito Destruction in Sierra Leone. II. The Effect of Treatment of Houses with "Gammaxane" on the Malaria-Rate in the Inhabitants. *Ann Trop Med & Parasit.* 1947 Sept., v 41 No. 2, 210-14.

By the (owl)-cell technique of Christophers, Sinton and Corvell, malarial parasite count distribution, in addition to parasite rate was estimated from the blood of children in the 0-10 years age-group in selected groups of villages before and five months after spraying with Gammaxane [see preceding abstract]

The results may be summarized as follows —

| Locality | No. Ex amined | Parasite Rate per cent. | Parasite-count distribution (No. per cent.) | | | |
|--------------------------|---------------------|-------------------------------|--|----------------------------|------------------------------|----------------------------|
| | | | 0-500 per cent. | 500- 1,000 per cent. | 1 000- 3,000 per cent. | Over 3,000 per cent. |
| <i>Coastal Villages</i> | | | | | | |
| Before treatment | 189 | 81.5 | 65 | 9 | 11 | 15 |
| After treatment | 111 | 80.2 | 50 | 9 | 20 | 21 |
| Untreated | 68 | 88.2 | 40 | 34 | 15 | 13 |
| <i>Interior Villages</i> | | | | | | |
| Before treatment | 222 | 83.3 | 54 | 17 | 19 | 10 |
| After treatment | 168 | 72.6 | 56 | 17 | 16 | 11 |
| Untreated | 51 | 0.6 | 91 | 6 | 3 | 0 |

It is clear that little difference in parasite rates and intensities occurred in the few months of observation.

[These papers do not lend themselves readily to abstraction, and should be studied in the original. Further researches in the field are in progress.]

RIJA, G. & GRAMPOCIA, G. Ricerche sulla infezione degli embrioni di pollo con *Plasmodium gallinaceum* (I nota) [Infection of Chick Embryos with *P. gallinaceum*] *Riv di Parasit.* Roma. 1947 June-Sept., v 8 Nos. 23, 119-24 2 figs. [12 refs.] English summary (6 lines)

The authors attempted to inoculate 25 embryo chicks from the 9th to the 17th day of incubation. Heavily infected blood was applied to the chorio-allantoic membrane and a small quantity was injected into the vitelline sac. Only two of the chickens, both of the 9th day acquired an infection. The infection developed rapidly death occurring on the 5th day after hatching. The parasites, which revealed an abnormal morphology were readily inoculable to other chickens the parasites then regaining their normal appearance.

G. M. Waryns

KROPPERS, A. T. Acquired Resistance (Twofold) to Quinine in *Plasmodium gallinaceum*. [Correspondence.] *Nature*. 1947 Nov 1 606-7

It was recently shown by BISHOP & BIRRETT and by WILLIAMSON & AL. [this Bulletin 1947 v 44 969-970] that *P. gallinaceum* maintained in chickens

could acquire resistance to paludrine. The present author has obtained similar results, but in contrast to the findings of the latter authors an acquired resistance was also demonstrated in the case of quinine. This result was obtained by inoculation of a 7-day-old chick with 50 million parasites followed by treatment with the minimal effective dose of the drug given once on the day of inoculation and twice on each of the three following days. Reinoculation of a fresh host was carried out with the blood of a treated animal on the same day each week. After treatment of the chickens with 10 mgm /kgm of quinine base in the form of hydrochloride, as in the above dosage schedule, some resistance was apparent after 12 weeks. After a further 16 weeks' treatment with double the dose, the course of the infection was scarcely influenced. The degree of resistance was found by experiment to be twofold. After one passage of the resistant strain through *Aedes aegypti* this acquired resistance to quinine was partially lost. The quinine-resistant strain showed no such character towards mepacrine paludrine, or chloroquine.

RAGER, W. The Relation to the Course of Avian Malaria of Biotin and a Fat-Soluble Material having the Biological Activities of Biotin. *J Exper Med* 1947, June 1, v 85 No 6, 663-83, 6 figs [36 refs]

In a previous paper [this *Bulletin*, 1943 v 40, 825] the author produced evidence that deficiency of biotin lessened the resistance of chickens and ducks to malaria infections. He subsequently found [*Proc Soc Exper Biol & Med*, 1947, v 64, 129] that the plasma of various animal species after hydrolysis with acids or enzymes contains a fat-soluble material designated FSF, having the biological activity of biotin, but differing from it chemically and which is not inactivated by the avidin of egg white. This substance could replace biotin as a growth factor for *Lactobacillus casei*. Its biotin activity has been used to measure the concentration of the substance, possibly a lipoprotein, from which it arises. Its properties suggest that it is concerned with resistance to infection. Chicks infected with *P. lophurae* and ducks infected with the same parasite or *P. cathemerium* were used in these experiments. The various diets used, which were adequate or deficient in biotin, are described. During malaria infections, the changes in concentration of biotin and of FSF in plasma and organs were measured by a biological method with the use of *L. casei*. Free biotin and FSF were measured in untreated plasma. The difference between that value and the one obtained after hydrolysis gave the value for bound FSF, biotin itself being unbound. The early inhibition of multiplication of *P. cathemerium* in ducks moderately deficient in biotin was paralleled by the deficiency of riboflavin and pantothenate in other malaria infections of chickens and by vitamin C deficiencies in monkeys, being due probably to the absence of a specific growth factor for the parasites. The higher peak of infection finally reached in deficient hosts suggested that another factor was at work, which interfered with some defence mechanism of the hosts, other than leucocytes. The concentration of bound FSF in plasma during infection varied to some extent like that of biotin, but the return to normal levels was longer delayed. Whereas the presence of excess free biotin is not associated with a limitation of parasite multiplication, high levels of bound FSF appeared to be associated with increased resistance to parasite growth. After malaria infections, the biotin content of the livers of deficient animals was reduced. In experiments with *P. lophurae in vitro*, in which the biotin content of the medium varied widely, the rate of parasite multiplication was not affected. The addition of α and β globulin fractions from human plasma having a 2 per cent concentration of FSF caused haemolysis and degeneration of the parasites. Similar effects have been noted with

fractions of animal plasma. The results support the view that the PSF fraction arises from a substance, probably a lipoprotein which is associated with resistance to malarial avian infection and acts against parasites and sensitized erythrocytes.

J D Fallon

BLACKWATER FEVER

KOLFF W J with the cooperation of J VAN NOORDWIJK. *The Artificial Kidney* 92 pp. 46 figs. 4 plans (1 folding) 1 chart & 5 sketches. [21 refs.]. 1946. Kampen, Holland J H. Kok NV.

It is not improbable that the accumulation of diffusible metabolic products in the blood is a contributory cause of death in acute uraemia. The removal of such retention products from the blood stream during the period of acute renal failure might help to keep the patient alive until such time as normal renal function is re-established. This book describes in considerable detail a method of removing such products from the blood by dialysis, by the use of a machine which the author has called "the artificial kidney". Other methods, such as irrigation of the peritoneal cavity and perfusion of isolated loops of gut, have occasionally been tried with some success. Kolff's method is based on extra corporeal dialysis of the patient's blood by a method rather similar to that previously described by Abel and his colleagues [ABEL, ROWNTREE & TURNER, *J Pharmacol.* 1913 v 5 275]. The machine consists of a cellophane tube 30-45 metres long wrapped round a rotating cylinder a portion of which is immersed in rinsing fluid which is a solution of sodium chloride (0.6 per cent.) sodium bicarbonate (0.2 per cent.) potassium chloride (0.04 per cent.) and glucose (1.5-2.0 per cent.). Arterial blood from the patient is passed into the cellophane tube and returned, after dialysis, by means of a cannula inserted into the patient's vein. The artificial kidney can deal with up to half a litre of blood at any one time and large quantities of blood can be dialysed in it in a short period. Thus in one case 80 litres of blood passed through it in under 12 hours. Kolff has reported the use of his artificial kidney in 17 cases of chronic and acute uraemia. In this series there were 2 recoveries. He has since reported 8 additional cases with 3 more recoveries [*Lancet*, 1946 Nov 16 726]. Extra-corporeal dialysis of blood in large volumes appears now to be a practicable proposition provided the apparatus is to hand. As was pointed out in the leading article in the *Lancet* [1946, Nov 16, 720] Dr Kolff "has provided evidence indicating that in some cases dialysis may tide the patient over a period of acute renal failure and keep him going until renal function is restored. The technique should be of value in those cases of potentially reversible renal failure which have been called renal anoxia [MARGRAITH HAVARD & PARSONS (this *Bulletin* 1945 v 42, 968)] in Britain and lower nephron nephrosis" in America, [*Lancet Med. Surgeon* 1946 v 99 371]. It is hoped that one day the opportunity may arise to test this technique in anuric blackwater fever.

B G Margraith

GOODYEAR, W E. & BEARD D E. *The Successful Treatment of Acute Renal Failure by Peritoneal Irrigation.* *J Amer Med. Ass.* 1947 Apr 19 v 133 No. 16, 1208-10 2 figs.

The possibility that death, in acute renal failure of a reversible kind, may be due to the accumulation of substances normally excreted by the kidneys, has given rise to the development of several methods of removing such substances from the blood, and so prolonging life until the kidneys can recover sufficiently

to resume function One of the techniques which has lately been stressed is based on a method of dialysis of the patient's blood by a machine which has been called the artificial kidney by its designers (KOLFF and BERK, *Acta Med Scandinavica*, 1944, v 117, 121), [see also above] This consists of a "cellophane" tube partly immersed in a solution of sodium chloride, sodium bicarbonate, potassium chloride and glucose Blood from the patient is passed through this apparatus from a cannula in the radial artery, and back into the body by a cannula into a vein of the foot or forearm In this way, substances such as excess urea are dialysed

The present authors have used an alternative method and have utilized the NaCl 8.0 gm KCl 0.2 gm, CaCl_2 0.1 gm, MgCl_2 0.1 gm, NaHCO_3 1.0 gm, peritoneum as the dialysing area The irrigating fluid contained (per litre), sodium biphosphate 0.05 gm, dextrose 1.5 gm, heparin 0.5 mgm, penicillin 5,000 units, and sulphadiazine sodium 0.1 gm Catheters were inserted into the peritoneal space and the incision was closed The irrigating solution was admitted to the peritoneal cavity by a drip method The average rate of irrigation was 500 cc per hour for two days, and 300 cc per hour for the two following days The technique was tried in a white woman who developed a reaction subsequent to transfusion following a nephrectomy The reaction was complicated by suppression of urine and rapidly increasing azotaemia Peritoneal irrigation was instituted 84 hours after the nephrectomy, and continuous irrigation was maintained for 4 days The azotaemia was rapidly reduced and the urinary output rose from 20 cc to 240 cc per day There was remarkable clinical improvement The non-protein nitrogen of the blood reached 100 mgm per cent within 3 days of the discontinuation of the peritoneal irrigation, but the urinary output steadily rose and the patient made an uninterrupted recovery The urea content of the recovered peritoneal washings varied from 47 to 53 mgm per cent The urine excreted after a resumption of renal function had a urea content of 100-140 mgm per cent and a specific gravity of 1.010-1.012 [The interest of this case from the point of view of tropical medicine lies in the possible application of such methods to cases of renal failure of the renal anoxic type occurring, for example, in blackwater fever or cholera It is possible that an artificial kidney of the type described by Kolff and Berk might give more satisfactory results as far as dialysis of the blood is concerned] [A case of peritoneal irrigation for uraemia after an incompatible blood transfusion is described by MUIRHEAD *et al* (*Arch Surgery*, 1947 v 54, 374) Ed]

TRYPANOSOMIASIS

NIGERIA Sleeping Sickness Service Annual Report 1946 *Nigeria Rep on Med Services for Year 1946* 22-9 1947 London 4 Millbank, SW 1 [9d]

Abstracted from a mimeographed copy, in this *Bulletin* 1947 v 44 973 5

NODENOT, L Note sur le traitement de la maladie du sommeil par la pentamidine [The Treatment of Sleeping Sickness with Pentamidine] *Bull Méd de l'Afrique Occidentale Française* 1946, v 3, No 2 215-26 [23 refs]

Results obtained with pentamidine [presumably the isethionate], in the treatment of sleeping sickness at Bobo-Dioulasso since 1944 may be summarized in the table below, constructed from the author's text

First series. Followed for 6 to 10 months some for more than 1 year

| Type of case | | Pentamidine treatment, i.m. repeated for 3 doses* | Cases | Possibly cured | No improvement† | Relapsed |
|--------------|--------------------------|---|-------|----------------|-----------------|----------|
| Early | Previously untreated | 2 mgm./kgm. | 78 | 73 | 2 | 1 |
| | | 3 " | 4 | 4 | | |
| | Reinfection | 2 " | 2 | 2 | | |
| | Arseno-resistant relapse | 2 " | 3 | 3 | | |
| | | 3 | 1 | 1 | | |
| Late | Previously untreated | 2 followed by trypanamide‡ | 10 | 5 | 5 | |
| | Chemo-resistant§ | | 9 | 2 | 7 (6) | |

Second series. Followed for shorter periods than the first series.

| | | | | | | |
|-------|-------------------------|-----------------------------------|----|----|--------|--|
| Early | Previously untreated | 4 mgm./kgm. | 60 | 56 | 4 | |
| Late | Slightly altered c.s.f. | 4 | 10 | 4 | 6 | |
| | | 4 †† | 3 | 2 | 1 | |
| | | 6 | 7 | 4 | 3 | |
| | | 6 †† | 2 | 2 | | |
| | Much altered c.s.f. | 4-6 plus intrathecal treatment‡§ | 14 | 0 | 14 (6) | |
| | Chemo-resistant§ | 4 mgm./kgm. | 20 | 4 | 16 (2) | |
| | | i.m. plus intrathecal treatment‡§ | 21 | 0 | 21 (9) | |

*On alternate days for 1st series daily for 2nd series.

†Number of deaths shown in brackets.

‡Course of 10 intravenous injections.

§Previously unimproved by treatment with arsenicals and serum.

**Details of c.s.f. changes not stated.

††Re-treatment of uncured patients of group immediately above. Treated 1 month after end of previous course.

‡Using 1 per cent. pentamidine, further diluted in c.s.f. in the syringe before injecting. First cases treated with 3 doses of 16 mgm. given after 1st, 3rd and 5th i.m. injections. Later cases treated with 1 or 2 doses of 10 mgm.

The author concludes that a dose of 2 mgm./kgm. pentamidine per injection is hardly sufficient, and 3 mgm./kgm. is recommended. In high dosage the

drug is effective up to, but no later than, the time when the infection begins to involve the central nervous system
 Intrathecal treatment is extremely toxic, and generally aggravates the infection

LEISHMANIASIS

LUENGO ARROYO E NÁJERA ANGULO, L & LOZANO MORALES A Problema sanitario de la leishmaniosis visceral mediterranea en España (Ponencia oficial) [The Problem of Visceral Leishmaniasis in Spain from the Sanitation Aspect] *Kuba Habana* 1947, Aug, v 3, No 8, 167-77, 1 fig

Since the report of PITTALUGA and VILÁ of the finding of cases of infantile kala azar in Spain in 1912 some 2 000 cases have been recorded In the year ending 31st May, 1946, there were 138 noted in 13 Provinces, the most, 31, in Jaén, next, 28, in Toledo, fewest, one only, in Madrid
 The authors consider the question of geographical distribution (just related) the aetiology, diagnosis and treatment, the epidemiology and prevention
 Diagnosis was made on clinical, haematological and serological grounds, such as the globulin tests of Brahmachari, the ureastibamine test of Chopra and Das Gupta, the antimony-formol test of Nattan-Larrier, the sulpharsenol test of Caminopetros, and others, or by the intradermo-reaction or by deviation of complement, by spleen or marrow puncture The authors have nothing fresh to add on the subject of treatment As regards epidemiology they suggest that besides the dog, the squirrel *Xerus getulus*, may be a reservoir host
 H Harold Scott

KIRK R & LEWIS, D J Studies in Leishmaniasis in the Anglo-Egyptian Sudan IX Further Observations on the Sandflies (*Phlebotomus*) of the Sudan *Trans Roy Soc Trop Med & Hyg* 1947, July, v 40, No 6, 869-88 2 maps & 2 figs [44 refs]

The collecting of sandflies in the Sudan by the oiled-paper method has resulted in the finding of 25 species of *Phlebotomus* these are listed and the bionomics of some are described
P langeroni var *orientalis* is the only one of the *P major* group whose distribution is related to that of kala azar in the Sudan Its occurrence is erratic and variable and may have some bearing on the erratic and variable

occurrence of kala azar. Unpublished observations revealed the anterior development of the parasites in gorged females which had fed on a patient with post-kala azar dermal leishmaniasis.

The common outdoor species *P. chylei* bites man in and out of doors. In experiments, the development of flagellates has been observed in one out of forty specimens, but the development was not of the "anterior" type.

The commonest and most widely distributed species is *P. signatipennis* but it feeds on geckos and seldom or never on man.

P. papatasi readily bites man indoors and has also been observed to bite outside.

The authors have made a special study of the haunts of *Phlebotomus* adults, particularly of holes and cracks in the ground. From observations and trapping experiments, they have accumulated considerable evidence that a vast subterranean environment exists in the Sudan plains, consisting of animal burrows in the sandy parts and of cracks in the heavy clay known as "black cotton soil". These are adult resting places, but whether they are also breeding places is not certain as no thorough search was made for immature stages.

H S LACON

ANSARI, N. Leishmaniose experimentale à *L. tropica* chez la souris. [Experimental Leishmaniasis produced in the Mouse by *L. tropica*.] *Bull. Soc. Path. Exot.* 1947 v 40 Nos. 3/4 82-6 4 figs. on 2 pls.

Using a strain of *L. tropica* isolated in culture (N.N.N. medium) from facial lesions of a girl suffering from Oriental sore the author inoculated 108 young white mice by intradermal, intratesticular and intraperitoneal routes. Intradermal injection at the base of the tail produced in 4 out of 8 mice cutaneous lesions at the site of inoculation in one case accompanied by visceral infection. Intraperitoneal injection of 22 mice resulted in a generalized infection varying in severity in 17 cases. The most constant positive results were obtained after intratesticular inoculation of 78 mice, 67 of which acquired a generalized infection while in 6 cases the infection was restricted to the testes. In each of the above series, a number of mice were refractory. The incubation period of experimental leishmaniasis in mice varied from 60 to 90 days. As a rule the mice succumbed to the infection in from 88 to 188 days. The occurrence of parasites, as revealed in smears, varied in different organs and tissues which are arranged in the descending order of frequency as follows: testes, ganglia, spleen, liver, peritoneum, bone-marrow, kidneys, lungs and suprarenal glands. The histo-pathological findings which are described in detail, can be summarized as follows. At the point of inoculation there appears a granuloma consisting mainly of macrophages loaded with leishmanias. The granuloma undergoes secondary necrosis and gives rise to a lesion closely resembling that of oriental sore in man. This localized lesion is followed by a generalization of the pathological process, which spreads to the spleen, ganglia, bone-marrow, liver and lungs involving the reticulo-endothelial system exclusively: the cells of which are packed with parasites. This process of infiltration representing a veritable parasitic blockade is accompanied by proliferation of cells of the reticulo-endothelial system which is especially marked in the spleen and liver giving rise to histo-pathological changes resembling those in kala azar. [The paper is illustrated by 3 photographs and one photomicrograph.] C A HOWE

SEAGER, L. D. & CASTELNUOVO GINA. Toxicity of Stilbamidine. "A Study of the Effects of Chronic Intoxication." *Arch. Pathology*, 1947 Sept., v 44 No. 3 287-96, 4 figs. [Refs. in footnotes.]

The toxic effects of stilbamidine on animals have been reported by number of workers [this *Bulletin* 1940 v 37 700 1943 v 40 683 1945 v 42, 18

1946, v 43, 1029] The present authors have investigated the histological changes produced by this substance after different dosage schedules in 160 rabbits and 100 mice. Many organs and tissues were studied, but the changes, chiefly degenerative, were most marked in liver and kidney. Detailed descriptions are recorded for these organs in animals killed at various intervals after drug administration. The nervous system was not investigated. Rabbits were treated subcutaneously with the drug and mice by the same route as well as by stomach tube. The doses ranged from 10 to 100 mgm per kilo and were given in single or multiple injections. During treatment rabbits lost weight, had diarrhoea and suffered from weakness, congestion of the iris and fall in blood pressure. Attempts to counteract these conditions were not successful. Blood sugar estimations indicated a hyper- or hypoglycaemic condition at different times, those for blood urea nitrogen were inconclusive while the van den Bergh test became positive after a short time. The chief change in the blood picture was a shift to the left in the leucocyte count, nucleated red cells were sometimes seen. Mice proved more tolerant of the drug, but changes comparable with those seen in the rabbit tissues were noted. There appeared to be no correlation between dosage and the histological picture.

FEVERS OF THE TYPHUS GROUP

BUSTAMANTE, M E & VARELA, G. Distribución de las rickettsiasis en Mexico (Tifo murino, tifo clasico y fiebre manchada) [Distribution of Rickettsial Disease in Mexico (Murine and Epidemic Typhus and Rocky Mountain Spotted Fever)] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1947 Mar, v 8, No 1, 3-14, 5 maps & 3 figs [17 refs] English summary

The incidence in Mexican States of the three rickettsial diseases in question is discussed and shown in a table. In each case the presence of the disease was established by the isolation of strains or by complement fixation or both. Murine typhus was found in 18 States and epidemic typhus in 19 which included 12 which also had the murine type. In the States of Durango and Sinaloa murine typhus and Rocky Mountain spotted fever were both present, in Coahuila all three rickettsial diseases were found, in San Luis Potosi and Vera Cruz both epidemic typhus and spotted fever were identified and the latter was also isolated in Sonora. The distribution of the three diseases singly and together, are shown in 4 maps, and the mortality from typhus in Mexico between 1931 and 1942 is shown in another map. In the north and north-east regions of Mexico, *Rhipicephalus sanguineus* was found naturally infected with the virus of Rocky Mountain spotted fever, on the east coast, the vector was *Amblyomma cajennense*.

RAYNAL, J H. La rencontre des *Proteus* à l'occasion du typhus de Chang-Hai [The Incidence of *Proteus* Strains during the Epidemic of Typhus Fever at Shanghai] *Bull Soc Path Exot* 1947, v 40, Nos 7/8 294-304, 1 chart [11 refs]

H J O'D Burke-Gaffney

No strains of *Proteus* were isolated from any of the 300 blood cultures made between 1938 and 1945 in Shanghai during the early stages of attacks of fever which were afterwards found to be due to typhus infection. From animals experimentally infected with typhus rickettsiae large numbers of heart-blood cultures were made after death, *Proteus* organisms were isolated

from 10 per cent. of the white mice examined, from 1.7 per cent. of the white rats, and from only one of several hundreds of the guinea-pigs.

From wild rats, about 3 000 blood cultures were made—only eight strains of *Proteus* were isolated, but 71 strains were isolated from bone-marrow cultures and 148 from urine cultures.

Among the 301 strains isolated in all the above experiments, 17 behaved like *Proteus* OX19 in agglutination tests—eight like P OXK and one like P OXE. An unstated number reacted in a manner suggesting that they belonged to types intermediate between *Proteus vulgaris* and *Proteus* X.

DE ROSNAY D. Etude de la moelle osseuse dans le typhus exanthématique. [The Bone Marrow in Epidemic Typhus.] *J. Méd. de Bordeaux*. 1947 Oct. v 124 No 10 480.

In 48 cases of epidemic typhus, the author studied specimens of bone marrow obtained by sternal puncture. He states that the myelogram obtained is characterized by changes in the red cell and myeloid systems and particularly by a definite proliferation of reticulo-endothelial and other elements. These changes are early and, the author states, give the myelogram a very characteristic appearance. Nevertheless, he admits that the changes are not specific but they do indicate a reticulo-endothelial response of an intensity rarely encountered in other infections—hence he considers that they have some diagnostic value in difficult cases.

By means of special staining techniques such as hot Giemsa or Giroud's application of Macchiavelli's method, cellular inclusions may be seen in some reticulo-endothelial cells in marrow smears—these inclusions recall the forms described by GIROUD and PANTHER [this *Bulletin* 1942, v 39 753] in the lungs of animals inoculated intratracheally with rickettsiae, and named by them homogeneous bodies.

The author is not prepared, however, on a simple morphological similarity alone, to assign a rickettsial nature to the inclusions seen in the bone marrow in epidemic typhus. Nevertheless, as these appearances are not seen in normal marrow nor in persons suffering from other infections, they have a considerable diagnostic value in the haematological study of epidemic typhus.

SANDOR, G. & GIROUD, P. Nature de l'agglutinine anti-typhus du sérum de lapin. [The Nature of the Anti-Typhus Agglutinins of Rabbit Serum.] *C. R. Acad. Sci.* 1947 Oct. 20 v 225 No. 16 704-5.

The authors have studied the distribution of the anti-typhus agglutinins in the protein fractions of the serum of rabbits inoculated through the respiratory route with typhus rickettsiae.

Three different euglobulin fractions were isolated from the rabbit serum whereas only two could be isolated from human and equine sera.

One of the euglobulin fractions from each of the above three sera was found to contain the greater part of the anti-typhus agglutinins, but this fraction in the case of the rabbit was not the same as in the case of man or the horse.

For the technical methods employed the original paper must be consulted.

SUTORISOVA-STULBOVA, Marguerite. Action sensibilisatrice de l'alexine au cours de l'agglutination des rickettsies. [The Sensitizing Action of Complement in connection with the Rickettsia-Agglutination Reaction.] *C. R. Soc. Biol.* 1947 July v 141 Nos. 13/14 719-20.

The sensitivity of a formal-killed rickettsial suspension used in carrying out the rickettsia-agglutination test was found to be increased two to eight times.

by the addition of complement [In one of the seven tests of which details are given, the rise in the titre was only from 1-40 +++ to 1-40 ++++] John W D Megaw

GIROUD, P & JUDE, A Conservation du pouvoir agglutinant vis-à-vis des rickettsies des sérums typhiques saturés par le *Proteus OX19* [Retention of the Rickettsia-Agglutination Potency of Typhus Serum after Absorption with *Proteus OX19*] *C R Soc Biol* 1947, July, v 141, Nos 13/14, 721-2

Agglutination tests were carried out on epidemic-typhus serum and on the same serum after absorption with a suspension of a culture of *Proteus OX19* which had been heated to 100°C for 60 minutes. The untreated serum agglutinated *P OX19* at a titre of 1-1,280, whereas after absorption the titre was only 1-80.

In rickettsiae-agglutination tests in which *Rickettsia prowazeki* and *R mooseri* were employed, the titres with untreated serum were 1-1,600 for both organisms, with the absorbed serum, they were 1-3,200 and 1-6,400 respectively.

Three samples of murine-typhus serum were tested in the same way, and with similar results, the absorption of the *OX19* agglutinins tended to increase rather than diminish the rickettsial agglutinins, so it was concluded that specific differences existed between the *Proteus* and rickettsial agglutinins.

HORTOPANU, D Gangrenele tifosului exantematic [The Forms of Gangrene in Exanthematic Typhus] *Rev Stimpelor Med* Bucharest 1947, Jan-Apr, v 36, Nos 1/4, 114-24 French summary

The author, in Rumania, reports on the presence of gangrene encountered on 25 occasions among 465 cases of exanthematic typhus seen since 1941. He divides these varieties of gangrene into the following three groups, which he regards as being quite distinct, aetiologically, clinically and therapeutically.

1 *Gangrene from thrombo-arteritis obliterans* of the large arterial vessels is seen especially in the legs. It is unilateral and results in necrosis involving almost the whole limb, but it is fortunately rare, and only 2 cases were seen, in persons of 2½ and 19 years respectively.

This condition begins abruptly with violent pain in the affected limb after 5 to 6 days of ischaemia, signs of dry gangrene appear. The affected part necroses and is completely mummified in 20 to 30 days. The slough separates in a strikingly clear-cut manner from the healthy living tissues, and this contrast is much more marked than in any other form of gangrene. By the time this has occurred, amputation is confined almost to the dividing of bone, which appears stripped of tissue. Perifemoral sympathectomy or section of the lumbar sympathetic (Leriche's method) should be tried, but are only successful in the first 6 to 8 hours. Acetylcholine should be given at the beginning of the ischaemia, although its effects are rarely marked.

2 *Gangrene limited to the extremities* is distinguished from the preceding variety by its causative lesions, which are the ordinary affections of arterioles as seen in exanthematic typhus. These are seen only in the winter in patients suffering from cold and malnutrition. Unlike (1) above, this form of gangrene begins insidiously and is limited entirely to the extremities, usually the toes. It is bilateral, and sometimes symmetrical. Necrosis is always superficial. Treatment is wholly conservative and surgical intervention is contraindicated in this form.

3 *Thrombo-angitis obliterans* (Bürger) is regarded by the author as a late complication of typhus, which should be taken into account in making a prognosis.

H J O D Burke-Gaffney

SMADIEL, J. E. SNYDER, J. C. JACKSON Elizabeth B., FOX, J. P. & HAMILTON H. L. Chemotherapeutic Effect of Acridine Compounds in Experimental Rickettsial Infections in Embryonated Eggs. *J. Immunology* 1947 Oct., v 57 No 2, 155-71 4 figs. [32 refs.]

During the war reports were received that Fumigander in Germany had found certain acridine drugs effective in preventing the death of mice experimentally infected with murine typhus. The chief substances tested by the authors were nitroacridin 3582 and an arsenical salt of this, called rutenol (see this *Bulletin* 1947 v 44 1057). The tests were carried out on groups of embryo chicks infected with one of the following strains of rickettsiae *Rickettsia prowazekii*, *R. mooseri*, *R. orientalis* and *Dermacentor* [Rickettsia] *rickettsii*. Both of the substances, when injected in suitable doses into the yolk sacs of embryos inoculated with rickettsiae, produced a definite rickettsiostatic effect and a pronounced delay in the death of the embryo.

Unfortunately the ratio between the therapeutic and toxic doses of the drugs was low 1-2 to 1-4 whereas for *para*-aminobenzoic acid it was about 1:10. The paper which contains details of a large number of experiments, will be read by all workers on the chemotherapy of the typhus fevers. A useful bibliography with references to 32 articles is appended.

John W. D. Meager

RAVENHILL, S. F. The Treatment of Rocky Mountain Spotted Fever with Para-Aminobenzoic Acid: a Comprehensive Plan. *Southern Med. J.* 1947 Oct. v 40 No. 10 801-11 7 charts. [15 refs.]

A detailed description is given of six cases of Rocky Mountain spotted fever in which *para*-aminobenzoic acid (PABA) was given with strikingly good results.

The total daily dosage recommended by the author is 0.5 gm. per pound of body weight for large children this amount is given in divided doses every two hours 1.0 gm. per pound is needed for very small children. Every dose is buffered with 10 cc. of a 5.0 per cent. solution of sodium bicarbonate for each gramme of the drug. In exceptional cases the patient refuses to swallow the medicine and gavage is needed. The treatment is kept up till three or four days after the fall of the temperature.

The blood level of the drug should be estimated daily at exactly the same time in relation to the administration of the previous dose. It should be maintained at between 30 and 60 mgm. per 100 cc. levels above 80 mgm. are risky.

If the total white-cell count falls below 3,000 per cmm. the drug should be stopped. Abdominal distension and delirium are not infrequently caused, but they are rarely of serious importance.

Details are given of the general treatment which includes —(1) the preliminary restoration of the fluid and electrolytic balance by glucose in saline given intravenously (2) maintenance of this balance by fluids with added sodium chloride by the mouth (3) correction of acidosis when necessary by parenteral injections of sodium lactate and (4) a diet containing abundant proteins and vitamins.

CAUGHY, J. E. & DUDGEON, J. A. "Q" Fever. A Serological Investigation of a Group of Cases previously reported as Primary Atypical Pneumonia. *Brit. Med. J.* 1947 Nov 1 684-5.

An outbreak in which 511 cases of "primary atypical pneumonia" occurred between February and April, 1945 among British and New Zealand troops in

the Naples-Caserta area was described by ADAMS *et al* [*Bulletin of Hygiene*, 1946, v 21, 288] Nearly two years later, sera were obtained from 20 of the 50 persons whose attacks had been specially studied Nineteen of the 20 sera gave positive reactions to the complement-fixation test for Q fever at significant titres ranging from 1-4 to 1-128 The tests were carried out by Dr N H Topping of the National Institute of Health, Bethesda, U S A , the antigen used was an Italian strain of *Rickettsia burneti*

The outbreak, therefore, appears to have been one of Q fever, of which several outbreaks occurring later in the Mediterranean area were closely studied by American workers, and were identified by the isolation of *R burneti* and by other tests Abstracts of 11 papers in which these investigations are described will be found in this *Bulletin*, 1947, v 44, 62-71

The paper contains a succinct account of the incidence, clinical features, and epidemiology of Q fever in the Mediterranean area, where the disease—though not fatal—caused great concern to the allied medical staffs because of the occurrence of numerous outbreaks in 1944 and 1945

[Since this abstract was written there has come to hand the September 1947 number of the *Archives of Internal Medicine*, which contains (p 413) a letter from GROSSMAN, referring to a paper by him in those *Archives* [see *Bulletin of Hygiene*, 1946, v 21, 572] This paper was an article "purporting to describe an outbreak of primary atypical pneumonia observed in Italy in 1944" On comparing his cases with those of ROBBINS and RAGAN and FEINSTEIN *et al* [this *Bulletin*, 1947, v 44, 62, 66], Dr Grossman now believes that his cases also were those of Q fever]

John W D Megaw

COMBIESCO D, VASILIU, V & DUMITRESCO, N Identification d'une nouvelle rickettsiose chez l'homme en Roumanie [Identification of a New Rickettsial Disease in Man in Rumania] *C R Soc Biol* 1947, July, v 141, Nos 13/14, 716-17

In the late winter and early spring of 1947, the author observed several patients whose symptoms suggested that they were suffering from a "new disease" From the blood of five of the patients, two strains of rickettsiae were isolated by passage, first through guineapigs, and then through chick embryos. Suspensions of blood and organs of the infected guineapigs were still infective after filtration [no details are given of the candles used]

The symptoms were similar to those observed in the various outbreaks of Q fever mentioned in the above abstract, so the authors conclude that the disease was analogous to, if not identical with, Q fever or "Balkan grippe"

John W D Megaw

BARTONELLOSIS

RICKETTS W E Carrion's Disease A Study of the Incubation Period in Thirteen Cases *Amer J Trop Med* 1947 Sept v 27, No 5, 657-9

Much controversy has arisen in the past regarding the incubation period of Carrion's disease, which has been variously estimated as being from a few days to several months Most of these early studies were made in the absence of cultures for *Bartonella bacilliformis*

The author studied 13 cases of the disease in different hospitals in Lima Peru, between 1938 and 1942 in all *Bartonella* was demonstrated in the blood, either by culture or direct smear

All the patients had been healthy before becoming exposed to *Phlebotomus* in the endemic area There were two groups In one, there were seven persons

who had only been in endemic zones for a few hours to three days this incubation period was thus accurately estimated. It varied from 20 to 23 days in four cases, and in the other three it was 40, 88 to 90 and 100 respectively. Details are given of two such cases.

In the second group of six persons the incubation period could only be estimated approximately as the persons remained permanently in the endemic area. In these, the period of incubation varied from 19 to 30 days, indicating that infection occurred during first exposure.

The author discusses the former difficulty in establishing the incubation period of Carrion's disease which is attributable mainly to the limited number of observations, the lack of reliability of patients' histories, and the varying symptomatology of the disease.

The vague symptoms met with in the initial stage of atypical and subclinical cases are often interpreted by patients as flu and gastro-intestinal upsets. In the present series, the finding of *Bartonella bacilliformis* in blood cultures taken during these apparently non-specific episodes made diagnosis possible. In Oroya fever the marked anaemia and slight jaundice, with *Bartonella* in the peripheral red blood cells, permit of an early diagnosis.

The author points out that the above findings agree with the result of experimental human inoculations. The first made by Carrion himself indicated an incubation period of 21 days. In the second, KUCZINKI-GONZALEZ observed initial symptoms 17 days after he had inoculated himself.

DENGUE AND ALLIED FEVERS

PAVLOVSKY E. N. *Pappasii Fever and its Vector*. State Medical Publication. 90 pp. 35 text figs. 1947 Leningrad. [In Russian.] [3.75 Roubles]

The aim of this book is to provide Russian medical officers with a guide to sandfly fever which in the Soviet Union is endemic in the Crimea, in Southern Ukraine, Transcaucasia and Middle Asia. A historical introduction, dealing with the achievements of Russian workers in the study of the disease during the last 25 years, is followed by a chapter in which sandfly fever is defined and data are given regarding its geographical distribution, aetiology, course of infection, diagnosis and treatment. Short chapters are devoted to the properties of the virus and to questions regarding susceptibility of lower animals to the infection. The greater part of the book is concerned with various aspects of the epidemiology of the disease, particular attention being devoted to the vector *Phlebotomus papatasi*, the development and bionomics of which are described in some detail. These data are used as a basis for sandfly control, including methods of protection and destruction employed against these insects, which are fully described. The systematic application of these measures for the prophylaxis of sandfly fever has already resulted in a marked diminution of the incidence of infection in Sebastopol. A separate chapter deals with immunity in sandfly fever.

This book, which provides in concise form all the essential information regarding sandfly fever, is a useful addition to the literature on tropical and subtropical diseases.

C. A. Hoers

PLAGUE

PUBLIC HEALTH REP Wash 1947, Sept 12, v 62, No 37, 1336-40 **Plague Infection reported in the United States in 1946**

No human case of plague was reported in the United States in 1946, nor has one been notified since 1943 (except for a laboratory infection in San Francisco in 1944)

During the year, plague infection was found in wild rodents or their ectoparasites from 9 counties of California and 1 county each in Oregon, Kansas and Texas. The proved area of infection in wild rodents in the western United States was extended further east by positive findings in tissues from a prairie dog, and in a pool of fleas from these animals, in Scott County, Kansas.

Details of these field surveys are given in a table. It is emphasized that the reports "are at best, essentially sampling procedures" conducted by some six or seven field units of the U.S. Public Health Service in 12 states. A hunting area in the field usually covers some 5 to 25 miles.

Plague infection was proved during the year in tissue specimens or ectoparasites from species of ground squirrels, chipmunks, field mice, grasshopper mice, white-footed mice, rats, kangaroo rats, prairie dogs and a cottontail rabbit.

H. J. O'D. Burke-Gaffney

HOEKENGA, M. T. **Plague in the Americas** *J Trop Med & Hyg* 1947, Oct, v 50, No 10, 190-201, 3 figs (1 map) [Numerous refs.]

At the beginning of this review are a most useful map and a most useful table. The former shows throughout the Americas in differential shading the areas of human and sylvatic plague respectively. In the latter there are set out countries in the American continent where human cases of plague were first reported, the source of original infection, the year in which the last human case was reported and other useful data. Most of the events given in short summaries for the separate countries have already been published. Two factors in the perpetuation of plague in wild rodents are noted for the readers' attention: (1) chronic or latent infection of the rodents, demonstrated especially in squirrels (*Citellus beecheyi*) by organ pool methods, and (2) lengthened infectivity of fleas for periods such as five months and even 396 days. Some special clinical manifestations are commented on, while therapy is treated under the headings: sulphonamides, penicillin, streptomycin and serum. Several new control methods are being developed, among which the rodenticides α -naphthyl thiourea ("Antu"), carbon disulphide and sodium fluoracetate ("1080") have been found efficient. As a pulicide, DDT applied with "1080" is probably the method of choice in epidemics. Prophylactic immunization fell into disrepute in Latin America but has again taken its place as a control measure. It appears to have taken the form of a killed vaccine grown on agar at room temperature. Abundant references to the literature for all the countries separately are provided.

W. F. Harvey

BARRETO, J. de B. & DE CASTRO, A. **Aspectos epidemiológicos da peste no Brasil** [Epidemiology of Plague in Brazil] *Mem Inst Oswaldo Cruz* 1946 Sept, v 44, No 3, 505-27, 2 coloured charts [28 refs.] English summary.

Epidemiological data which could be usefully comparable have not been available in Brazil for very long. They have, however, increased in usefulness during the years since 1941, when progressive improvement in the prophylactic service has taken place, and especially since 1943. Some of the increase in plague, manifest in 1944 and 1945, may have been due to the more accurate

record of the disease. Laboratory diagnosis has been one of the factors in the accuracy these laboratories were 6 in 1943 and now number 21. A classification of plague cases was adopted with categories (a) positive, (b) suspected and (c) negative. Some of the older data were salvaged and kept under these headings, so that tables are presented from about the year 1881 onwards. Plague was first recorded as entering Brazil in 1899. Various tables are given by the authors illustrating epidemiological and clinical oscillations. The first table is an important one set out in 3-year periods in incidence 1934-36 1 247 cases 1937-39 301 cases 1940-42, 659 cases [shown elsewhere as 680] 1943-45 412 cases, revealing a decline coincident with the Federal Government's initiation of a campaign against plague in the east Brazil—the focal plague area of the country. The principal focus has been Pernambuco with 40 to 50 per cent. of the cases in the triennia investigated. Plague as a whole and this is a very interesting point, has shown three distinctive periods since its entry. In the first period, 1899-1908, plague attacked the principal ports, to pass in the second period to the cities of the interior. In the third period, which continues to the present day, plague is tending to disappear from the cities and to localize itself endemically in rural areas.

The population of the north-east of Brazil is mainly occupied in the cultivation and disposal of cereal crops, cotton, mandioca and a castor oil crop. These crops are stored in the houses and, together with the accession of dirt, become an attraction and shelter for rodents and their fleas.

In the quinquennium 1941-45 there were 749 cases of plague, for three of which there is no information. Many tables deal with the remaining 746 cases. Treatment was developed on modern lines and the sulphonamide drugs proved their efficacy while penicillin was discarded. In the tables furnished, care is taken to show that the percentages calculated were tested for statistical significance. Sulphadiazine was administered without plague serum in doses of 12 to 14 gm. daily for the 3 first days and of 8 to 10 gm. daily on subsequent days. The figures for laboratory diagnosis in the 748 cases, after deduction of 78 (10 per cent.) cases where this was impossible, show 342 (51 per cent.) confirmed positive while 329 (49 per cent.) were negative, although the latter were recorded as positive on clinical and epidemiological grounds. Medical opinion expressed disapproval of gland puncture as a method of diagnosis and recommended an increased employment of haemoculture, and inoculation of blood direct into the peritoneum of guinea-pigs. The method of choice for laboratory diagnosis *post mortem* was digitotomy to obtain bone marrow. This or gland juice or blood, was preferably sown in full-culture sulphite agar and thus despatched to the laboratory.

The vector of major epidemiological responsibility remains in Brazil as *X. cheopis* (temperate zone) where *X. brevipalpis* (tropical zone) is also present. Short chapters are devoted to the vector and to questions regarding susceptibility of lower animals to the infection.

The greater part of the book is concerned with various aspects of the epidemiology of the disease, particular attention being devoted to the vector *Phlebotomus papatasi*, the development and bionomics of which are described in some detail. These data are used as a basis for sanitary control, including methods of protection and destruction employed against these insects, which have been described. The systematic application of these measures for the control of sandfly fever has already resulted in a marked diminution of the disease in Sebastopol. A separate chapter deals with the epidemiology of sandfly fever in the region of the Black Sea.

This book, which provides information regarding sandfly fever in the subtropical diseases, is found on the 3 sub-species of *X. brevipalpis* (temperate zone) where *X. brevipalpis* (tropical zone) is also present. Of all the domestic animals, the most parasitized by *X. brevipalpis* is the dog, followed by the cat, and then the pig. The incidence of *X. brevipalpis* in the dog is 3 per cent. in S. Paulo (lat 23° S), 10 per cent. in Fortaleza (lat 3° S), and 15 per cent. in Rio de Janeiro (lat 22° S). The incidence of *X. brevipalpis* in the cat is 10 per cent. in S. Paulo, 15 per cent. in Fortaleza, and 20 per cent. in Rio de Janeiro. The incidence of *X. brevipalpis* in the pig is 10 per cent. in S. Paulo, 15 per cent. in Fortaleza, and 20 per cent. in Rio de Janeiro. The incidence of *X. brevipalpis* in the dog is 3 per cent. in S. Paulo, 10 per cent. in Fortaleza, and 15 per cent. in Rio de Janeiro. The incidence of *X. brevipalpis* in the cat is 10 per cent. in S. Paulo, 15 per cent. in Fortaleza, and 20 per cent. in Rio de Janeiro. The incidence of *X. brevipalpis* in the pig is 10 per cent. in S. Paulo, 15 per cent. in Fortaleza, and 20 per cent. in Rio de Janeiro.

ad, G Caractères des cultures secondaires obtenues par l'action du bactériophage sur le bacille de la peste A propos des mutations du bacille pesteux en bacille pseudo-tuberculeux [Secondary Cultures obtained by Bacteriophage Action on Plague and Mutation to the Pseudotuberculous Bacillus] *Ann Inst Pasteur* 1947, July, v 73, No 7, 642-9, 2 figs

argument that *P pseudotuberculosis* is only a variant or mutant of *P pestis* tries to make its appearance Girard's own experience is wholly opposed to this idea If, however, a bacillus is found which ferments glycerin and can also to ferment rhamnose, that bacillus if it has been isolated as a plague bacillus becomes of necessity the pseudotuberculosis bacillus (of Malassez and others) That this has been done by obtaining secondary colonies after phage action on *P pestis* is claimed especially by Russian workers Only once has Girard had occasion even to record what seems to have been a mutation of the plague bacillus under bacteriophage action It was in a fatal case of plague caused by bacteriophage, the organism isolated after death, in sharp contrast to that isolated from buboes before death, produced only lesions of chronic type in the test guinea-pigs It was, however, still a plague bacillus What explanation then is to be given of the antinomy? Girard points out that plague bacilli of sylvatic plague origin do acidify glycerin and if they do possess one of the peculiar characters of the pseudotuberculosis bacillus, it is reasonable to suppose that further deviations from type might, say under the action of bacteriophage, bring about the transformation Plague strains isolated from wild rodents, Russian spermophiles of the Steppes, ground squirrels in California and sometimes South African gerbils are the strains in question which are confronted, perhaps, by two differing groups of bacilli, the murine, which is the non-deviating plague bacillus, and sylvatic bacilli Girard concludes that extracts or filtrates of plague cultures are toxic for rats and mice whereas those of Malassez's bacillus are not, and that this test might now be brought into operation in order to clear up what is still obscure in the epidemiology and prophylaxis of plague

11, A da Costa & HATHAWAY, C R Pulgas Bibliografia, catálogo e lista de animais por elas sugados [A Bibliography of Fleas and their Animal Hosts] *Monografias do Inst Oswaldo Cruz* 1946, Dec, No 4, 522 pp 1946 Rio de Janeiro Imprensa Nacional

This large monograph comprises first a bibliography of books and papers on fleas, arranged chronologically, the first work quoted is dated 1544 and the last 1944 This is followed by a catalogue of the fleas of the world, the first of which is an index arranged according to families, subfamilies, genera and species The catalogue itself occupies some 240 pages, and for each species or subspecies is given extensive information (with references) on synonymy, and information on geographical distribution and on the species of animals which act as hosts This is followed by a section of over 80 pages in which the animal hosts are listed in scientific order, with the fleas found on each species tabulated under the species A general index to the whole work occupies over 100 pages Species are not described, but the work does not claim to be more than a catalogue, and it is, indeed, an admirable compilation which should prove to be most useful for reference The authors have largely followed the classification of WAGNER, as modified, in relation to the fleas of North America, by TRUING & FOX [this *Bulletin*, 1943, v 40, 841] For the nomenclature of the mammal and bird hosts the authors have followed well-recognized authorities

The work that has been put into this volume must have been very great indeed. There are a lot of fleas, and it is a solemn thought that, according to ESKY [this *Bulletin*, 1939 v 36, 310] any one of them is a potential vector of plague.

Charles Wilcocks

MEYERS F. M. Diagnostische moeilijkheden bij pest. [Diagnostic Difficulties in Plague.] *Med. Maandblad Batavia*. 1947 Aug. No. 13, 24, 3.

Difficulty in diagnosis of plague is frequently encountered by the clinician and epidemiologist having insufficient experience. The author instances as one example the case of several members of one family admitted simultaneously. The father had clinically and bacteriologically proved plague. One child had fever with small glandular swelling in both groins which were not typical buboes and were negative on gland puncture. The second child had moderate fever was mildly ill and had no buboes. All three recovered. There follows detailed description of two patients admitted as suspicious cases of plague, of whom one proved to be suffering from an anaerobic streptococcus septicaemia and the other from atypical pneumonia, probably due to the Friedländer bacillus. Enlargement of lymph nodes was a striking symptom in both cases and both had a periorbital oedema.

CHOLERA

MONTHLY BULL. MINISTRY OF HEALTH & PUB. HEALTH LAB. SERVICE (DIRECTED BY MED. RES. COUNCIL). 1947 Nov v 6, 198-203. Cholera. A Note by Medical Officers of the Ministry of Health.

A useful summary of the disease and its control.

CHRONICLE WORLD HEALTH ORGANIZATION 1947 Oct., v 1 No. 10 141-5. Cholera in Egypt.

This declaration of international health policy is an important, wise document of precautionary measures against epidemic disease as a whole, although directed against cholera in particular. The statement that, There is reason to believe that a century ago a similar epidemic could not have been checked, does not perhaps quite imply that it would have been checked in this century. A note of caution is sounded against measures of panic instituted in the name of precaution, even if they are only overprecaution, such as the complete closure of frontiers. In that example, much would depend on the type of frontier and the possibility that it would only provoke clandestine violation and thus promote the very occurrence legislated against. The argument, of course, can be applied to nearly all prohibitions if they can be or are, evaded.

All sanitarians are anxious to put into force immediate measures to counter immediate public dangers and the summarized list of commands here set out, twenty-eight in all, should be a very valuable guide in any communicable epidemic. It follows the usual lines and will, doubtless be transcribed and put into practice by responsible authorities. The summary may be still further abbreviated as (1) Isolation and observation of patients, contacts and local inhabitants. (2) Accelerated and enforced sanitary measures for disposal of refuse and defects. (3) Active and continued disinfection of dwellings, food and water. (4) Prohibitions on congregation and traffic of people, on the use of suspect or non-disinfected food and water on the use of public conveniences

or drainage systems with free communication into distributive water (5) Immediate inoculation of contacts and mass inoculation of entire populations at risk

Discussions have taken place among experts with all the evidence of friendly international cooperation. Most of the opinions expressed have been on traditional lines. [One would have welcomed also some opinion that the opportunity should be taken, internationally, to investigate—traditional views for their validity, their dependence on unconscious selection of data, their statistical significance, the question of endemicity, prescribed measures, not only for their efficacy but their degree of efficacy, by definitive search the existence of negative instances, and the use of some form of alternate case method. If sanely presented, such suggestions might escape the accusation of being inhumane and qualify for statistically-scientific status.]

Conventions which are now recommended are "(a) surveillance for travellers adequately protected by vaccination, (b) surveillance and medical examination for those who have not been vaccinated."

These are very reasonable, and would presumably be accompanied by the recommendation for continued research into their foundation

- iii. LANCET 1947, Nov 8, 697-8 **Anti-Cholera Measures in Egypt, from a Correspondent in Egypt**

i With the appearance of epidemic cholera and its threat to the valley of the Nile and the deltaic area, attention is inevitably directed to India, the traditional home of cholera. The Yangtse valley is too far distant to be considered in this connexion. It is not, however, the Ganges valley which is mentioned in this discussion, but the Punjab, where epidemic cholera started on August 15, 1947. The epidemiology of cholera was dealt with in a general and Indian sense by Sir John Taylor at a recent meeting of the Royal Society of Medicine. Upwards of 200,000 persons die of cholera in India every year. The routes of spread from this focus are (1) *via* Afghanistan to Persia and S E Russia, not now a major danger (2) *via* Iraq, Syria and Turkey to the Mediterranean, and (3) by the Red Sea to Egypt. Egyptian cholera is, or has been, linked with the annual pilgrimage to Mecca, but effective quarantine measures have, since 1912, eliminated this source of infection. Cholera patients and cholera contacts are probably the main source of cholera infection, apart from short-distance transmission extracorporeally, and both patients and contacts may excrete vibrios for about five days. The Egyptian epidemic, having reached a peak, should, like other epidemics, prophesies Sir Leonard Rogers, now die down though with some prospect of recrudescence next year. Among public health measures to be imposed in Egypt was, said Dr Melville Mackenzie, surveillance "on air passengers who had spent nights in Egypt." The rapid advance of air travel and the shortening of time involved seem to demand a significant alteration of quarantine measures, based as they have been upon an incubation period for cholera of five days and an average excretion of vibrios also for five days. Identification of the cholera vibrio was dealt with by Mr Bruce White and especially of the three types of cholera vibrio, described as "original, intermediate and variant." These variants or sports are transmutable, but not in the course of infection. Transmutation of non-pathogenic vibrios is another question altogether.

II. Dr Abdou deals with the course of the present epidemic in Egypt and contributes most interesting details. It started in El Kordin, a town of 15,000 inhabitants in the date-growing province of Sharkieh. Perhaps the most important point to note regarding the population is that it has been augmented by some 6000 immigrants settled there to work in British camps, and by 9000 others during the date season. No correlation between the present epidemic and the British forces is admitted by the authorities. In connection with the spread of the epidemic there is mentioned the case of an old woman in El Kordin who contracted cholera and who sent her grand-daughter to her mother in Demouh with a present of dates on October 1. The mother developed cholera and so the epidemic received its further impetus into the province of Dakahlieh. Dates and escaping settlers are incriminated as the agents of spread of cholera. It seems to have been proved that the cholera vibrio cannot live in compressed dates, but that it can live for some time on the skin of ripe dates. It is interesting to find a brief reference to the report of a medical commission sent to investigate the first cases of cholera in this region in the 1893 epidemic — Clinical and bacteriological examination has proved that the disease prevailing at El Salhiéh is a gastro-enteritis due to the over-eating of dates and salted fish. [Experience of cholera outbreaks in the river delta of Iraq during the date season in the first world war may be recalled.]

III. In this Egyptian epidemic, the main water supplies do not appear to have played any part in the spread, but the badly constructed shallow wells have been a factor in so far as the disease has been water-borne. It is because of their better water supplies and hygienic conditions that Cairo, Alexandria and the other big cities have largely escaped infection. The number of reported cases including suspects from Sept. 23 to Oct. 21 reached 8,308 with 3,230 deaths (39 per cent.) It seems to be too early yet to judge of the value of the newer methods of treatment employed, but restoration of the depletion of water, and presumably salt, is regarded as a sheet anchor. The prophylactic value of vaccination seems to be fully confirmed while experience with sulphonamides has been on the whole disappointing. A huge campaign is being carried out to vaccinate the whole population of Egypt. A vigorous use of DDT was instituted to combat the fly menace. It may be expected that still closer analysis of this epidemic will receive publication and may help to clear up the constantly recurring problems of distant transmission, endemicity and the variant vibrios.

W. F. Harvey

Bliss-Johnson is sounded against measures par les vibrios non proliférants of precaution even if they are only overgrowing Vibrios. [see Inst. Pasteur closure of frontiers. In that example, m. [13 refs.] frontier and the possibility that it would proliferating vibrios, suspended in course, can be applied to nearly all — (1) The speed of fermentation of glucose and of titratable acidity for times in parallel assumed, is more feeble in aerobiosis than in anaerobiosis, is especially marked with active aeration. The succinic acid found among the products of the cholera vibrio are derived mainly from the medium. (2) Quantitative studies have shown glucose consumed, is variable under aerobic and anaerobic conditions. It could not be used to differentiate betw. *El Tor* except under rigorously standardized conditions.

All sanitarians are anxious to put into immediate public use the findings for washed and boiled food at pH 8 and 10. The findings for washed and boiled food at pH 8 and 10. The findings for washed and boiled food at pH 8 and 10.

GALLUT, J Sur l'utilisation du glucose par le vibron cholérique en aérobiose forcée [Utilization of Glucose by the Cholera Vibrio under Forced Aerobiosis] *Ann Inst Pasteur* 1947, July, v 73, No 7, 650-59, 2 figs [13 refs]

Gallut pursues his researches [this *Bulletin*, 1943, v 40, 910, 1946, v 43, 129, 1947, v 44, 421 and 660] on the metabolism of the cholera vibrio and finds that both the toxic fractions are liberated in non-aerated glucose media. It follows that the utilization of glucose by combustion instead of fermentation has no effect on the liberation of toxin. His researches lead him to insist that the differences in the morphology of the vibrios as well as in their chemical structure require continued study before concluding that cultivation under the restraint of aerobiosis in glucose media will lead to increase in antigenic power, that is, to an improved cholera vaccine. The argument is, in fact, for study of the natural biological mode of growth of the cholera vibrio as it occurs in the human intestine, with a view to obtaining effective antigen for immunization.

Gallut finds advantage in using heated agar-grown, aerated-culture, suspension [LINTON and JENNINGS this *Bulletin*, 1945, v 42, 378, 379] as well as ordinary peptone water culture for comparison of the chief characteristics of his cultures of the cholera vibrio in glucose media, which are strictly aerobic and non-aerated. These characters are set out in a table.

Some characters of the cholera vibrios according to the method of cultivation
(24 hours at 37°C)

| | Culture in Buffered Glucose | | Culture in Normal Peptone Water | Emulsion of Culture on Agar (Vaccine) |
|---|-----------------------------|--------|---------------------------------|---------------------------------------|
| | Aerated | Normal | | |
| limits (mv) | | | | |
| Upper | +81 | +150 | +150 | — |
| Lower | +42 | —200 | —250 | — |
| limits | | | | |
| Upper | 8.32 | 8.0 | 8.2 | 8.0 |
| Lower | 7.05 | 6.6 | 7.6 | — |
| vibrios per cubic centimetre | | | | |
| milligramme (dry) | 0.909 | 0.240 | 0.914 | 0.750 |
| Number $\times 10^6$ | 4.848 | 1.280 | 4.874 | 4.000 |
| glucose broth (per cent) | 1.48 | 0.33 | — | — |
| total nitrogen (mgm per cc) | | | | |
| fluid | 0.109 | 0.150 | 3.523 | — |
| vibrios | 0.063 | 0.024 | 0.109 | 0.106 |
| nitrogen content of vibrios (per cent.) | 7.0 | 10.1 | 13 | 15 |
| antigen (mgm per cc) | 0.137 | 0.030 | 0.065 | 0.035 |
| nitrogen content of vibrios (per cent.) | 15.0 | 12.5 | 7.1 | 4.6 |
| nitrogen content of O antigen (per cent.) | 2 | — | 5 | 5 |

work confirms the adaptability of the cholera vibrio, which is normally facultative anaerobe, to a strict aerobiosis during the phase of growth. It utilizes glucose in aerated media at pH 7 to 8 and at slightly positive

oxidation-reduction potential (E_h 0 at 100 mv) by combustion instead of fermentation.

BURROWS W MATHER, Adaline N ELLIOTT Marian E. & HAYES, Imbelle. Studies on Immunity to Asiatic Cholera. III. The Mouse Protection Test. *J Infect. Dis.* 1947 Sept.-Oct. v 81 No. 2, 157-74 [30 refs.]

In newer methods of measuring degrees of immunity actual protection is expressed in terms of the proportionate survival of the test animals. The old measure of agglutinin titre is no longer favoured as a real index of the efficiency of vaccine or of serum. Guinea-pigs are costly when large numbers have to be used and it seems reasonable to make trial of the mouse yet mice are relatively resistant to the intraperitoneal inoculation of cholera vibrios in broth or saline suspensions. The incorporation of commercial granular mucin in the inoculum has, however, proved successful in overcoming the resistance of mice. The present experiments, which are very completely controlled and will be a source of reference for workers in the subject must be read in entirety.

As the passive protection test was more useful than the active, it has been studied in greater detail. Vibrios for inoculation were maintained by weekly subculture on blood veal infusion agar and preserved frozen or in lyophilized culture for inoculation they were measured as dry weight (2,000 million = 1 mgm.) Mice were inoculated intraperitoneally from suspensions of 24-hour culture at a concentration of 8 to 14 mgm./ml. and in a dose of 0.2 ml. of the dilutions made from it. The mice were observed after the challenge inoculation for 72 hours but only deaths up to 48 hours (which were less erratic than those up to 72 hours and showed sharper end-points) were taken into account in calculating LD₅₀ doses.

In the passive protection test the mice were challenged 6 to 24 hours after intraperitoneal inoculation of the rabbit immune serum. It was not worth while using a normal serum control and the number of LD₅₀ doses used was found from the ratio of the LD₅₀ of immunized mice to the LD₅₀ of untreated mice.

An important pronouncement is that in a sense the fatal infection of the mouse with cholera vibrios suspended in mucin is a highly artificial one, and it is not unlikely that the virulence of many common saprophytic (?) strains can be similarly enhanced. This is due, in part at least to the amount and toxicity of bacterial substance of the proliferating bacteria. The findings of this very technical paper are that (1) A standard

fold increase method of titration is not practical, but the antibody can be expressed as ratio of the LD₅₀ dose for immunized to the control normal mice within reasonable limits (2) Only a 10-fold increase in protective titre was significant a 10-fold antibody may be in part anti-endotoxic against O agglutinin. Little or no justification is shown between the experimental infection and human generalized bacteraemia in the latter the bowel with only minor and rare invasion of

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

NELSON, E C **Alcoholic Extract Medium for the Diagnosis and Cultivation of *Entamoeba histolytica*** *Amer J Trop Med* 1947, Sept, v 27, No 5, 545-52

A new medium for cultivating *Entamoeba histolytica* is described. It consists of an alcoholic extract of chopped tissue (guinea pig liver, cat intestine, egg yolk or almost any animal tissue), in the proportion of 1 part tissue to 9 parts of 95 per cent alcohol. The spirit is driven off by warming on a water-bath, and the residue is then mixed with melted 2 per cent agar buffered at pH 7.4 in 0.5 per cent saline. (The agar solution is in the proportion of two to one of the alcoholic extract.) The tubes are put up in a steep slant and an overlay solution of 0.5 per cent saline, buffered at pH 7.4, is added to each tube. Finally a loopful of rice starch is introduced into the medium at the same time as the inoculation.

A lump of infected faeces, the size of a pea, is placed in the tube, and subculture is made after 24 to 48 hours. Most intestinal protozoa grow in the first culture, but *E. histolytica* is the only parasite which survives in the later ones. The culture can be maintained for many months or years by weekly subinoculation.

The method can be employed as a routine diagnostic procedure, and gives better results than the direct methods. P C C Garnham

CHNEIDER, R F & SHIELDS, G W **Investigation on the Transmission of *E. histolytica* by Cockroaches** *Med Bull New Jersey* 1947, Oct, v 7, No 2, 119-21

The authors, working in Talara, Peru, made cultures of the legs and intestinal contents of 100 cockroaches (species not identified) in a search for viable cysts of *Entamoeba histolytica*. They used *Entamoeba* medium (Difco), to slants of which were added before use a mixture of 1 part of human serum in 6 parts of saline, sufficient to cover the surface. A 5 mm loop of rice powder was added to each tube. After incubation at 37°C for 48 hours, the "rice serum" was examined for the presence of *E. histolytica*.

No *E. histolytica* were found in specimens from the legs of the cockroaches, they were found in 7 per cent of the cultures from the intestinal contents. The authors conclude that food and utensils can be contaminated by viable forms of *E. histolytica* from the faeces of cockroaches and that the common cockroach can be incriminated as a carrier of *E. histolytica* in Peru. H J O'D Burke-Gaffney

RITA, G **Contributo allo studio della sierodiagnosi nell'amebiasi [Sero-diagnosis of Amoebiasis]** *Riv di Parassit* Rome 1947, June-Sept, v 8, Nos 2/3, 113-18. English summary

With an antigen prepared from blood and mucus of a case of acute amoebic dysentery by addition of seven volumes of alcohol and filtering after keeping at 45°C for fifteen days, complement-fixation tests were carried out on 63 cases of amoebiasis. A positive result was obtained in 92 per cent of the cases. It was found, however, that the antigen reacts with Wassermann-positive sera, and therefore negative sera are alone of value in the amoebiasis tests. C M Wenyon

RUDOLPH A M & BRAUDO J L **Amoeboma of the Large Bowel with a Review of the Literature** *Clin Proc Cape Town* 1947, Sept, v 6 No 7 287-91, 2 figs. [12 refs]

BRAS G. Amoebiasis van de vagina. [Amoebiasis of the Vagina.] *Ned. Maandblad*. Batavia. 1947 Sept. No. 14 200-61

The English summary appended to the paper is as follows —

Description of amoebiasis of the vagina, the portio uteri and the left labium majus in a 20 year old Javanese woman in a state of cachexia due to nutritional deficiency and intestinal amoebic dysentery

SHRAPKEL, B. C. Oral Emetine in the Treatment of Intestinal Amoebiasis. *Am. J. Trop. Med.* 1947 Sept. v 77 No 5 527-44

The drug used in this study was emetine hydrochloride, prepared by Eli Lilly Co., enclosed in capsules or enteric-coated tablets, administered orally. Each tablet contained one-third of a grain of alkaloid, designed to release emetine into the lower bowel approximately 3-4 hours after ingestion, thus avoiding the emetic effect of its presence in the stomach and upper intestinal tract. A total of 30 cases of intestinal amoebiasis were treated in this series, in age groups ranging from seventeen months to 66 years. These comprised acute and chronic dysenteries, as well as carriers.

No selection of cases was made, except that none was included if emetine hydrochloride subcutaneously had already been begun.

The standardized dosage schedule was as follows —

Children One tablet ($\frac{1}{3}$ grain) orally three times daily for 12 days. Total, 12 grains of emetine.

Adults Two tablets ($\frac{2}{3}$ grain) orally three times daily for 12 days. Total, 24 grains of emetine.

It was suspected that some tablets might pass unchanged through the intestinal canal, and this was found true in two cases in which tablets were seen in the rectal lumen during a proctoscopic examination.

The routine observed comprised daily examination and culture of stools, urine examinations, blood measure readings, complete blood counts every three days and proctoscopic examinations before and after treatment.

The children varying in age from 15 months to 9 years, comprised two cases of acute dysentery, two chronic and one carrier case. All presented the picture of secondary anaemia and harboured other intestinal parasites, particularly helminths. They were given vermifuges and purges in addition to oral emetine. One who was critically ill, and whose haemoglobin percentage was less than 10 per cent. required two blood transfusions.

None of the patients vomited or showed toxic manifestations during emetine treatment. The amoebae disappeared between the third and fifth days. Moderate diarrhoea, with pus cells in the faeces, was checked by sulphaguanidine in one case. A noteworthy side effect was the expulsion of large numbers of *Trichuris trichiura* in two patients as the result of oral emetine.

Twenty-five adults aged from 18 to 66 years were treated with two tablets of emetine three times daily for 12 days. They comprised 6 cases of acute dysentery, 13 of chronic and 6 of the "carrier" state.

Toxic symptoms were absent. Diarrhoea in the acute cases subsided and the number of stools was reduced to 2 to 3 daily. Abdominal cramps and tenesmus likewise subsided. Trophozoites of *E. histolytica* had disappeared on the third day but cysts were found as late as the sixth.

Amoebic ulcerations of the rectum underwent steady healing. In one patient, residual ulcers responded to sulphadiazine.

The author re-examined 24 of 30 cases after a lapse of 2-9 months.

The five children were re-examined 4 to 8 months after treatment. All appeared cured. The blood picture showed marked improvement of the secondary anaemia. Nineteen of the twenty-five adults were followed up for

two to nine months. There was only one failure in this series. All expressed themselves as feeling quite well. No cases of extra-intestinal amoebiasis were encountered.

It is claimed that though the present series is small, oral emetine, in the form employed, is easy to administer, does not produce toxic symptoms, and gives effective results.

ALDRICH E. C., FAVIER D. I. & GORDON F. S. *The Metabolism of Chloroform using Radioactive Iodine* *Proc. Roy. Soc. Med.* 1947 Sept. 27 No 5, 553-60-61-62.

This elegant piece of work deals with the metabolic fate of chloroform, (8-hydroxy-7-iodo-quinoline-5-sulphonate) which has been

widely used in the treatment of amoebiasis. In the sample used, stable iodine was replaced by radioactive iodine ^{131}I with a half-life period of 8 days, and details of its preparation are given. Radioactivity was measured by means of a Geiger-Müller counter with a uranium preparation as standard, and details were checked against a known weight of radiochloroform. The drug was given orally to seven fasting subjects, none of whom had amoebiasis, in single doses of 100 to 400 mgm. so that 0.5 millicurie of radioactivity was not exceeded. Blood was collected up to 8 hours after administration of the drug, and urine and faeces were collected for 2 and 7 days respectively. After the blood was freed from protein, measurements showed that activity was maximal 2 hours after ingestion and declined gradually to a negligible level in 8 hours. Part of the activity was due to iodide formed by degradation of the drug, and in the region activity was noted for approximately one day. The urine was separated into two fractions by chemical means, one containing all the activity of chloroform and iodide derived from it, and the other that of radiochloroform alone. The amount of chloroform excreted in urine and the extent to which it was degraded could thus be ascertained. A marked excretion occurred during the first three hours after ingestion and gradually tailed off; the total voided during the period of observation being about 12 per cent. of the administered dose, of which 7.4 per cent. was unaltered chloroform. The amount of iodine split from the parent substance increased as time went on. For the examination of faecal specimens, the samples were dried at 85-90°C. for 24 to 48 hours and in aliquot of 5 mgm. of the powder obtained was used for measurement of radioactivity. The amount recovered in faeces varied from 50-60 per cent. of the dose given. When added to that from urine, the total excretion was approximately 70 per cent. of the total dosage. The authors suggest that the incomplete recovery is due to failures in technique rather than to storage in the body. It is clear from the results that absorption of chloroform does occur fairly rapidly to the extent of 12.9 per cent. of the administered dose, but clinically significant blood levels are not attained.

J. D. Fulton

PRAMANIK, S. Balantidiasis [Correspondence] *Brit. Med. J.* 1947 Nov 15, 794.

Referring to SHUN-SHUN's article on the treatment of balantidial dysentery [this *Bulletin*, 1948, v 45, 84] the author has administered $\frac{1}{2}$ gram (11 mgm.) of bimodide of mercury intramuscularly to a patient suffering from this disease.

The illness had lasted for three months as many as 20 to 30 stools being passed a day. Four days later the stool examination was negative but the infection was repeated. Two subsequent examinations were negative, the patient then reporting the passage of two or three stools per day. C. M. Weryen

RELAPSING FEVER AND OTHER SPIROCHAETOSIS

KERVAN P. Recherches sur la sensibilité du poulet à *Spirochaeta duttoni*. Absence d'immunité de l'oiseau infecté contre *Spirochaeta gallinarum*. [Researches on the Susceptibility of the Fowl to *Spirochaeta duttoni*. Absence of Immunity against *Spirochaeta gallinarum* in Infected Birds.] Bull. Soc. Path. Exot. 1947 v 40 No. 5/6 152-5 2 charts.

Using a strain of *Spirochaeta duttoni* originally isolated from a case of relapsing fever at Dakar the author studied the behaviour of this spirochaete in fowls.

It was found that fowls varying in weight from 525 to 1400 gm. when inoculated intraperitoneally with the blood of a rat containing this organism, showed a rise in temperature on the 4th day associated with the presence of very numerous spirochaetes in the circulation for one to two days. With the use of blood containing visible spirochaetes it was possible to maintain the strain by passage in fowls.

The organism does not persist in the brain of the fowl and even in the blood seems to lose its infectivity for the white rat.

Seven fowls infected 3 to 5 months previously with *S. duttoni* were inoculated with *Spirochaeta gallinarum* and all showed numerous spirochaetes in the circulation, but recovered from the infection. E. H. nlla

LEVADITI, C. & VAISMAN A. Effets virulicides de la streptomycine dans l'infection récurrentielle de la souris (*Spirochaeta duttoni*). Comparaison avec la pénicilline. [Action of Streptomycin in Experimental *Trep duttoni* Infections in Mice compared with that of Penicillin.] C. R. Acad. Sci. 1947 Oct. 27 v 225 No 17 769-71

The authors found that subcutaneous administration of 5,000 units of streptomycin daily for 6 days sterilized the blood of mice which had been inoculated intraperitoneally with blood rich in *Trep duttoni*. The spirochaetes were absent from the blood of the mice during the 20 days of observation, but appeared in that of control untreated animals on the day after inoculation (and presumably remained there). Furthermore, brain substance from these treated mice failed to infect clean mice on intraperitoneal inoculation. The authors had already shown [this Bulletin 1947 v 44, 718] that large doses of penicillin, administered subcutaneously, failed to destroy the residual infection in the central nervous system of mice with long-standing *Trep duttoni* infections. In the present experiments, they were able to show that mice infected for 58 and for 84 days, administration of a total of 30,000 units of streptomycin subcutaneously prevented infection of clean mice by means of brain substance from these treated mice in from 62 to 78 per cent of cases. The brains of untreated control mice remained virulent. Mice infected for 103 days were treated with 160 units of streptomycin daily for 12 days by the intracerebral route. Brain substance, passaged 15 days after the beginning of treatment, failed to infect clean mice, but that of the untreated controls remained virulent.

In concluding that streptomycin, like penicillin, sterilized both the blood and the brain in mice infected with *Trep duttoni* the authors point out that, while

penicillin was inactive against residual central nervous infections in mice when given subcutaneously, streptomycin produced a partial sterilization of such residual infections by this route and a total sterilization when given intracerebrally

They suggest that either streptomycin penetrates the nervous tissues more readily and more intensely than penicillin, or that the residual cerebral infection is more resistant to the latter antibiotic than it is to streptomycin, investigation of these hypotheses is being carried out *H J O'D Burke Gaffney*

HALAWANI, A On the Transmission of Relapsing Fever in Egypt *J Egyptian Pub Health Ass* 1946, Nov, v 21, No 8, 183-90

The author discusses the classification of relapsing fever and describes the results of examination of lice, ticks, bugs, fleas and blood sucking flies during the epidemic of relapsing fever in Egypt in 1945 and 1946

He notes that body-lice, head lice and their developmental stages are the chief vectors of relapsing fever in Egypt

Spirochaetes were found in the coelomic fluid of a few bugs collected from houses feeding experiments indicated that the spirochaetes were capable of surviving in the coelomic fluid, but they were not found in as large numbers as in the case of lice

No ticks were found in any of the Egyptian houses examined, nor were fleas found to harbour spirochaetes *H J O'D Burke Gaffney*

OMAR, M El S Reinfection in Louse Borne Relapsing Fever *J Egyptian Pub Health Ass* 1946 Nov, v 21 No 8 191-4

An account of three cases

IVAN, I M & ILIESCU, G A Contributii la studiul elementelor figurate ale sangelui periferic si organelor hemato-poietice, in febra recurenta Europeana [Study of the Peripheral Blood and Haemopoietic System in Relapsing Fever] *Rev Stiintelor Med* Bucharest 1947, Jun-Apr, v 36, Nos 1/4 76-95, 3 figs [23 refs] French summary

OMAR, M El S Rare Complications of Louse Borne Relapsing Fever *J Egyptian Pub Health Ass* 1946, Nov, v 21, No 8, 195-200

The author records the study of 6,921 cases of louse-borne relapsing fever during the epidemics of 1945 and 1946 in Egypt

The commonest complication was abortion (92 per cent of pregnancies) the next commonest was bronchitis (8.6 per cent of cases) An unposing list of other complications is given and observations are made on twelve of them

AUBIN, H, GACHAEL, ZANGERLIN, Mme & GALLO, M Les troubles mentaux dans la fièvre récurrente [Mental Manifestations of Relapsing Fever] *Algérie Méd* 1947, May, No 5, 408-16

Relapsing fever was very prevalent in North Africa in 1944-45-46 The observations under review deal with the neurotropic effects of infection with *S obermeieri* The nervous types of the disease are classified as follows —

(A) *Confusional* — A certain amount of mental confusion is common, but in some cases a severe confusional syndrome, and not merely a temporary state, was observed, the patients being in a condition of extreme prostration, with no perception of time or surroundings, unable to understand questions or to answer coherently This form can result in acute delirium accompanied by terrifying

dreams and may show sudden and violent exacerbations. In one case (a Mahomedan Algerian) attempts to commit suicide by throwing himself out of the window were noted—these were caused, apparently by dreams of a terrifying nature. In some instances a form showing very severe prostration, usually ending fatally was observed. Usually in confusional cases an anxiety state was present.

(B) *Psychical*.—Maniacal forms are common and may occur as a primary manifestation or follow on a purely confusional state or on one of confusio-mania, or on confusion accompanied by an anxiety complex. In one instance (a young soldier) confusional symptoms appeared at the time of the second febrile attack, improvement occurring towards deservescence when typical maniacal state suddenly supervened. This patient recovered after 5 "electric shock" treatments. In another case (an Algerian) mania, accompanied by grandiose delusions, showed itself before the onset of pyrexia and improvement only occurred after 5 months. Irritability and impulsiveness, especially amongst natives, are other important symptoms in this type—a few electric shock treatments usually suffice to bring about cure.

The depressive form is very rare, having only been seen in one instance and then following on a confusional state.

(C) *Protracted types*.—Most writers hold that such types are rare, and chronic forms have not been noted. The authors report a case in a Spaniard who became stuporose at the commencement of pyrexia, appearing to have no realization of his identity. After 7 months he recovered use of his speech admitting having auditory hallucinations—later a diagnosis of paranoia was confirmed. This condition is now of 2 years standing.

The authors describe several cases showing that mental disorder may become chronic, in some cases ending in actual insanity. Electric shock treatment appears to be of benefit in certain instances. Various types, religious mania, delusional and hallucinatory forms are described in some detail.

The time of appearance of psychoses is variable and not necessarily in the precrisis of the first febrile attack. Mental symptoms were observed during the incubation period before any signs of infection appeared, and early psychotic forms may develop into mania long after disappearance of signs of infection. It is impossible definitely to separate primary psychoses from those due to the infection.

During the actual attack, confusional conditions with dreams and an anxiety state are most common, but, as noted, the first appearance may often be in the apyrexial phase with absence of spirilla in the blood, and hence one difficulty in diagnosis.

During convalescence mental symptoms tend to appear in more or less atypical forms—delirium with sudden onset and return of pyrexia—psychological troubles of a trivial nature, perhaps delayed for several weeks or months after cessation of pyrexia.

A history of various chronic infections or intoxications is often found, especially alcoholism, which in some cases gives rise to a syndrome resembling delirium tremens, and syphilis. Five patients showed positive Wassermann reactions—one of these after an attack of relapsing fever developed a mental syndrome of continued amnesia and poverty followed by signs of a tabetic type and a spasmodic paraplegia (syndrome of Guillain and Thoen).

[Some authorities hold that relapsing fever does not give a positive W. R. in the blood, others hold a contrary view.]

[Possible mental complications in relapsing fever are worth bearing in mind from a medico-legal aspect in regions where this disease is prevalent.]

EL-RAMLY, A H Three Papers on Louse Borne Relapsing Fever I Treatment of Louse Borne Relapsing Fever *J Egyptian Pub Health Ass* 1946, Nov, v 21, No 8, 125-49 II Splenic Infarctions *Ibid* 150-65, 3 charts III Report on 139 Fatal Cases of Louse Borne Relapsing Fever *Ibid* 166-82

The author of these three papers is Director of the Fever Hospital, Imbaba, Egypt

¹ This paper records the study of 856 cases of louse-borne relapsing fever, 684 of which were treated with different arsenicals and 172 were kept as control

The patients were divided into ten groups and each of nine groups was given a different treatment schedule with varying doses of NAB, Mapharsen, Mapharside and Glyvarsenyl the tenth group served as a control

Details are given of the results obtained in each group, in terms of fall of temperature, disappearance of spirochaetes, relapses and mortality details of five fatal cases are given

The final results of all the treatment schedules are shown in a table the author does not, however, attempt to analyse them comparatively, and as several factors require to be taken into account, the table should be studied in the original

^{II} In 3,000 consecutive cases of louse-borne relapsing fever, infarction of the spleen was found in 75 (2.5 per cent) there were 28 deaths Most of the patients were between 20 and 65 years and males predominated The condition is easily missed it occurred mostly in the original attack and first apyrexial period

In 52 cases the infarctions were simple the remaining 23 were septic

The signs and symptoms are discussed, and full details are given of four patients Arsenical drugs were not found to be of use in treatment or in preventing occurrence of infarction penicillin may prevent sepsis, if it is given early during the stage of simple infarction

^{III} Between January and July 1946, there were 7,379 cases of louse-borne relapsing fever admitted to Embaba Fever Hospital [this is printed earlier in the *Journal* as "Imbaba"] Of these, 273 patients died Autopsies were carried out on 139 of the fatal cases, and the results are discussed at length. It is noted that in 8 cases, foetuses of from 6 to 8 months were born prematurely, showing characteristic post-mortem signs of relapsing fever all the mothers concerned had showed the specific spirochaete in their peripheral blood, and were actually suffering from relapsing fever at the time of miscarriage

The morbid anatomy of relapsing fever, and of the complications found, is discussed and the records of 11 cases are given *H J O'D Burke-Gaffney*

HARTMAN, F W Further Observations on Leptospirosis in Micronesia *Science* 1947, Sept 26, 294

This records information additional to that given by ALICATA [this *Bulletin*, 1947, v 44 665] The investigation was carried out in this case on the island of Yap, in the Western Carolines, south and west of Guam

In Yap Town, 28 rats were trapped alive, these comprised three species, *Rattus alexandrinus*, *R. norvegicus* and a third, provisionally identified as *R. vulans micronesiensis* Pieces of kidney, removed immediately after each rat was killed by drowning, were preserved in 10 per cent formalin for several months and were then stained by a silver precipitation technique No spirochaetes were found in any of the kidney sections

The author concludes (although the number of specimens was small) that murine leptospirosis is not present in that area, possibly because Yap is geographically isolated If, however, *L. icterohaemorrhagiae* was once introduced

Vol 45 No 2]

42 years against 32 to 66 in the Spanish-American war, this also suggests that in the more recent wars infection occurred in foci in the U S A where the infected persons had been born. Most of the patients from Louisiana have been of French origin

L Rogers

CHAUSSINAND, R Contribution à l'étude de la morphologie du bacille de Hansen [The Morphology of Hansen's Bacillus] *Ann Inst Pasteur* 1947, July, v 73, No 7, 660-65

In the course of his prolonged studies the author has distinguished four distinct morphological forms of leprosy bacilli, as follows: normal bacilli are rod shaped, sometimes with pointed ends, they are of variable length and stain uniformly by Ziehl's method. Secondly, bacilli undergoing evolution are large, occasionally branched and with thickened ends and they do not always stain uniformly. They are found especially in macules and tuberculoid infiltrations and nerve cases which are showing resistance and tending to cure. They are not found in progressive lepromatous cases. They are also present in inoculated animals showing resistance to infection. Thirdly, bacilli undergoing division are divided into two or three nearly equal lengths by small unstained transverse intervals where they divide by fission, they may show some granulation. They are never found in nerve cases not undergoing evolution and are less frequent in treated than in untreated cases; but they are present in large numbers in globi in active cases of leprosy with rapid multiplication of the organisms. Fourthly, in degenerating lepra bacilli, disintegration takes place by progressive stages with the appearance of lightly staining granules in the rods, followed by gradual loss of staining power and the appearance of chains of granules, which in turn disintegrate to minute dots and then disappear. This last form increases *pari passu* with the clearing up of cutaneous cases under treatment. No proof has yet been furnished of the existence of an ultra-microscopic form.

[It may be of interest to recall that the reviewer, in 1917, recorded and illustrated increased granulation of lepra bacilli and their gradual disintegration and disappearance from nodules of the ears, with improvement under treatment by injections of soluble preparations of chaulmoogra oils (this *Bulletin*, 1918, v 11, 407)]

CHAUSSINAND, R A propos des essais de culture du bacille de la lèpre [Attempts at culturing Leprosy Bacilli] *Ann Inst Pasteur* 1947, May v 73, No 5, 433-8 [14 refs]

This is a valuable summary of over 1,000 attempts to cultivate lepra bacilli in the course of ten years, with suggestive tests for the true organism to enable others to avoid the common fallacies of the hundred or so former workers who have incorrectly claimed success. SOULE and MACKINLEY appear to have come nearest, by obtaining minute colonies of the causative organism, but no one has obtained a series of subcultures. Readers should consult the original for a bibliography of former attempts and for a summary of the numerous culture media unsuccessfully employed by the present author. He concludes that workers have been misled through an apparent increase in the bacilli, with gradual dissolution of leprous tissue cells inoculated on media, and the carrying over of many of them on subculture. What may possibly have been a very slow appearance and increase of colonies of acid-fast bacilli with the characteristic appearance and arrangement of Hansen's bacillus may have been obtained occasionally, but subculture has proved difficult or impossible. The author advises the use of the following two tests to determine whether any apparent cultures are true leprosy bacilli or not: (1) The intradermal injection of

suspensions of Hansen's bacillus killed by heat gives negative local reactions after two weeks in lepromatous leprosy and positive reactions in tuberculous leprosy. On the other hand, similar injections of tubercle, paratubercle or Stéfanaky's rat leprosy bacilli give more or less intense positive reactions in the case of all lepromatous persons who are sensible to tuberculin. (2) When Hansen's bacilli are injected into the general body cavity of the larva of the wax moth (*Galleria mellonella*) they are phagocytized by giant cells, but are digested very slowly so that they can be stained and easily recognized several days later in the insects. But tubercle bacilli and saprophytic acid-fast paratuberculous bacilli, formerly so frequently mistaken for Hansen's bacillus, are rapidly disintegrated and disappear from the giant cells within a few days. The use of these tests will enable the true character of any cultures obtained from the leprosy tissues to be determined.

[The larva of the wax moth *Galleria mellonella* is regarded as the guinea pig of insect microbiology and has been utilized in phagocytic studies of many bacterial species, owing to its varying capacity for phagocytic response to the inoculation of bacteria and other foreign particles. See also CAMERON *J. Path. & Bact.*, 1934 v 38 441 and STEINHAUS, *Insect Microbiology* 1948 568 Comstock Publishing Co. New York.—Ed.]

L. Rogers

CHAUMINAND, M. Inoculation de la lèpre aux animaux. [Animal Inoculation with Leprosy Material.] *Ann. Inst. Pasteur* 1947 July v 73 No. 7 677-82.

The author summarizes in this paper ten years' experience of inoculations of animals with leprosy material. In the case of white mice subcutaneous inoculation of material containing very numerous lepra bacilli produced only local lesions and alopecia but three animals which survived intraperitoneal injections later showed scattered bacilli in the internal organs. Monkeys have also been inoculated by various routes. Intradermal and subcutaneous injections have produced local lesions only after three to five months—these disappeared again before long and left no trace nor was any multiplication of the bacilli found. Lepromatous nodules were implanted in the subcutaneous tissues, with the production of purulent lesions which healed slowly and were of an eliminative nature and not true infective lesions. However the insertion of a leprosy nodule into the peritoneal cavity did produce an infection, with the appearance of cutaneous lesions containing acid-fast bacilli—the tuberculin test was negative, but the Mitsuda was positive. Later the lesions resolved with progressive disappearance of the Hansen-like bacilli from the tissues, and the Mitsuda reaction became negative. Inoculation of lepromatous emulsions into guinea pigs by various routes gave no results, as the bacilli were eliminated more or less quickly. On the other hand, the insertion of a leprosy nodule under the skin of the nape of the neck produced a local infection.

The author concludes that the inoculation of animals with leprosy material does not produce infections of a general nature, such as would afford opportunities for testing the value of therapeutic substances used in the treatment of the human disease.

L. Rogers

ORDEMAYER, M. E. Diffuse Lepra. *Ann. Western Med. & Surgery* 1947 Aug. v 1 No. 6 225-31 6 figs.

The author has had a large experience of this dangerous and easily overlooked form of lepromatous leprosy since it accounts for as many as 60 to 70 per cent. of all lepromatous cases in parts of Mexico where he works and 17 per cent. in other Mexican areas. As the disease develops slowly with indefinite and not easily recognized symptoms, it easily escapes detection, yet is highly

Helminthiasis

Vol 45 No 2]

infective After discussing the differences between lepromatous and tubercloid types of leprosy, the author describes the pure diffuse lepromatous form. Cutaneous nodules are absent and there is a diffuse infiltration of the skin of the whole body and a peculiar lepra reaction described by R LUCIO as an *erythema necroticans*. Lucio called this form "spotted" or "Lazarine" lepra as early as 1851, and LATIPI studied it further in Mexico in 1937. The unique lepra reactions appear three or four years after the onset of this type of the disease as tender and painful erythematous and slightly infiltrated small macules on the extremities and face, which develop central necrosis leaving superficial, sharply circumscribed atrophic scars, these lesions are illustrated by five photographs. Osseous destruction may result in a saddle nose, but the eyes are not affected. The eyelashes and eyebrows are frequently lost and alopecia of the scalp may follow. Progressive weakness ensues with death, occurring after an average of eight years, the Mitsuda reaction remains negative throughout, indicating absence of resisting power. Numerous lepra bacilli are found in the diffusely infiltrated skin in all parts of the body, unfavourable reactions follow the use of chaulmoogrates or iodides.

TISSEUIL, J Deux types de lèpre cutanée tertiaire, dermique rouge en nappe, hypodermique blanche en nodule [Two Types of Cutaneous Tertiary Leprosy] *Bull Soc Path Exot* 1947, v 40, Nos 5/6, 147-9

The author describes red and white tertiary cutaneous leprotic lesions which he thinks are liable to be confused. The red form occurs particularly on the body in the form of extensive, isolated thickenings or nodules of a yellow or red colour showing necrosis and very numerous lepra bacilli on section, and it may cicatrize to leave white radiating scars, it tends to develop rapidly.

On the other hand, the white lesions are more frequent on the face and extremities in the form of isolated nodules up to the size of an almond, these are situated in the subcutaneous tissue and freely movable under the dermis which is pale white. They contain numerous polynuclear cells and lepra bacilli and tend to soften and discharge through the skin, leaving ulcers which heal slowly. They are easily excised and have a fibrous coating, they discharge many bacilli and have a longer duration than the red form.

HELMINTHIASIS

ELSDON-DEW, R. Zinc Sulphate Flotation of Faeces *Trans Roy Soc Trop Med & Hyg* 1947, Oct, v 41, No 2, 213-16, 1 fig

The zinc sulphate flotation technique of FAUST *et al* [*this Bulletin*, 1939, v 36, 144 *ibid* 1940, v 37, 62] is coming into increasingly prominent use for the concentration of ova and cysts in faeces. It has, however, the disadvantage that trophozoites of protozoa are destroyed by the repeated centrifugation

(1305)

The author in Durban, compared this technique with the direct faecal film in the examination of 1,539 routine specimens of stools, derived mostly from cases of suspected amoebiasis. For the reason noted above findings for protozoa refer to cystic forms only.

The results are clearly set out in the form of two tables and a chart—one of the former shows the exact findings of six species of protozoa and six species of helminths, by the direct and flotation methods, separately and together; conflicting results with the double techniques are also shown, together with the totals of all positive findings. The second table indicates the relative efficiencies of each method, singly and together and includes a column showing the ratio of positive results by the zinc method to that of the direct, expressed as percentages. The chart compares graphically the proportion of positive findings, in the form of appropriately shaded circles.

Four hundred and twenty (36.8 per cent.) specimens were negative by both methods; in the remainder there was considerable variation in the total of positive findings, from 6 and 11 in the case of *Chilomastix muris* and *Schistosoma mansoni* to some 200 in the case of *E. histolytica* and *E. coli* and hookworms, and some 600 in the case of *Ascaris* and *Trichuris*.

For a statistical appraisal of the results, the tables should be consulted—but it may be said that, on the whole, there was a striking gain in positives for nearly every species of parasite when the zinc sulphate flotation was used. Protozoal cysts floated well, especially those of *Iodamoeba butschlii*; the absence of faecal debris made ova and cysts easy to find.

Nevertheless, some ova did not usually float well, especially those of *Ternstroemia* and *Schistosoma mansoni*—they were often found in the final centrifuged deposit.

The author calculates that the average overall gain obtained by the use of Faust's zinc sulphate flotation amounted to 179 per cent. In the case of hookworm, *Giardia* and *Iodamoeba butschlii* it was over 500 per cent. The technique is a very valuable diagnostic aid in the examination for intestinal parasites—but the author believes that the direct film still remains the method of choice, since trophozoites may also be detected with its use. Where possible both techniques should be employed.

H. J. O'D. Burke-Gaffney

DR MILLON B. *Aspects of the Natural History of Bilharzia in South Africa.*
Read at a Medical Congress, East London, South Africa, 1947. 6 pp.
[17 refs.]

This paper read at a medical congress in East London, South Africa, is an able summary of the position as regards human schistosomiasis in the Union. *Schistosoma haematobium* is found throughout the whole Transvaal north of about 28°S. and there is a strip of country also infested, down the coast as far as Port Elizabeth. Snails capable of acting as intermediate hosts exist in areas hitherto unaffected by the disease, but the increase which is taking place in the movements of labourers may bring infection to new areas. *Schistosoma mansoni* was hardly known in the Union in 1934 but since then indigenous cases have been found in Natal, N.E. Transvaal, Central Transvaal, Eastern Transvaal, and Swaziland. This infection is apparently spreading actively having been introduced from the north.

The author remarks on the difficulties experienced in the identification of molluscs and on the scarcity of experts on the subject. In the Union, the following molluscan hosts have been found for *S. haematobium*—*Physopsis africana*, *Physopsis globosa*, *Bulinus tropicus*, *Bulinus forskellii* and (doubtful) *Lymnaea natalensis*. The host of *S. mansoni* is *Planorbis* (*Blompharion*)

Helminthiasis

Vol 45 No 2]

pfeiffer The author gives a list of places where these snails are found, they are much more widely distributed than the corresponding schistosomes.

The ecology of these snails has not been studied systematically, and there is a need for research on this subject. It is, however, known that snail-spawn is deposited on aquatic plants, and may be transported considerable distances on the legs of wading birds, it is also known that some snails prefer mud rich in organic matter such as faeces. There is a general impression that rivers running west in the Union are not dangerous in respect of schistosomiasis, and thus is arguably true, because the rivers are in their natural state, perennial, with sandy bottoms and subject to violent flushing so that there is little true aquatic vegetation, snails do not flourish in such streams. If these rivers are dammed, however, they will become suitable for the snails.

The author gives a detailed description of the laboratory techniques for identification of cercariae from wild-caught snails, for infection of laboratory snails, and for their maintenance. These details must be sought in the original paper.

The paper ends with a warning that the great industrial development planned for the Transvaal, which will involve a large increase in population and which has already led to the impounding of water in the Vaal river, may mean a very great spread of schistosomiasis if the relevant snails become established, the prospect, if this happens, will be grim. The author also notes that African immigrants from tropical areas are not permitted to settle in urban areas, and that they therefore seek the small farms close to towns, and may infect the snails in the waters about those farms.

- 1 BASSÈRES, M S & PANTOJA, W P Esquistossomose — Prevalência de *S. mansoni* na população humana [The Prevalence of *Schistosoma mansoni* in Man in Part of Minas Gerais, Brazil] *Rev Serviço Especial de Saúde Publica* Rio de Janeiro 1947, v 1, No 1, 135-48, 1 fig & 1 map English summary
- ii — & — Esquistossomose Prevalência de *S. mansoni* em Planorbídeos [The Prevalence of *Schistosoma mansoni* in Planorbid Snails in Part of Minas Gerais, Brazil] *Ibid*, 149-62 [12 refs] English summary

1 The authors examined faeces from 5,314 persons (about 15 per cent of the population) along the Victoria-Minas railway. The specimens were examined by the Stoll-Hausheer technique. Part of the route lies along the Rio Doce, and three zones were recognized. The first lay away from the river, and here the proportion of persons infected with *S. mansoni* was 0.9 per cent. The second zone lay entirely along the river, with an index of infection of 21.1 per cent. The third zone lay partly along the river, and partly away from it, where the railway diverges from the main stream, and in this zone the index of infection was 12.9 per cent. Incidence reached its peak in the age group 15-24, and was rather greater in males than in females at all ages.

The infection rates in planorbid snails (see below) varied from nil to 11.1 per cent. Details of the findings are set out in a series of tables.

ii In connexion with the investigations in man referred to in the preceding abstract, the authors examined 5,248 planorbid snails taken in the three zones. Most of the snails were *Australorbis olivaceus*, a well-known intermediate host of *S. mansoni*, but other genera were also examined, in small numbers. In Zone I, where human infection is light, no infected snails were found, and in Zone III in only 1.4 per cent of 517 specimens. The snails were found chiefly in creeks, springs and ditches, and there was evidence that they may

spread from the main streams of the Rio Doce up the tributaries. The basin of the Rio Doce apparently constitutes a single unit in relation to schistosomiasis.

- II. — & — Larval Cycle of *Schistosoma mansoni* in its Small Intermediate Host, *Australorbis glabratus*. Kuba, Habana. 1947 Mar., v 3, No. 3 69-72, 5 figs.

1. "1 The miracidium of *S. mansoni* bears a close resemblance to that of *S. haematolum*. In addition to other structures described in previous accounts, it is also provided with an anterior *terebatorium* and pairs of antero-lateral and postero-lateral papillae. What has been described by others as clusters of lateral secretory glands with their corresponding ducts, is believed to be ganglionic nerve cells and nerve tracts that run to the antero-lateral papillae. A germinal epithelium has not been observed.

"2. The miracidium penetrates into the molluscan host by actual perforation of the epiderm of the head-foot organ the tentacles, or the mantle collar. On rare occasions, a larva may gain access to the shell cavity and from there penetrate and settle in rather distant locations.

3. The snail may be simultaneously parasitized by numerous miracidia. However during the first days of infection many will fail to develop, so that the number of mother sporocysts in multiple infections is smaller than the number of miracidia that actually penetrate.

4. Implantation and subsequent development occurs close to the point of entrance. Within five hours the miracidium loses its motility and sheds its ciliary membrane. By the twenty fourth hour the germ cells in the larva begin to divide. The parasite may then be called a mother sporocyst.

"5 By the forty-eighth, many of the mother sporocysts may appear as fairly elongated, simple, thin-walled sacs full of germ cells. The body begins to develop transverse constrictions that make the parasite appear like a series of separate chambers. Beyond the second day and up to the twentieth, the sporocyst grows markedly in length, becoming an intricate organism with numerous constrictions and convolutions. Essentially however it is a long, thin-walled tube. There is no evidence of motility in the mother sporocyst *per se*. Migration of this stage through the snail tissues is therefore, highly improbable.

6. Whenever the mother sporocyst develops close to the surface of the head-foot organ in the tentacles, or in the mantle collar of the snail, a permanent tumefaction arises. The swelling becomes perceptible on the fourth day of infection and grows in size with advancing age.

7. The daughter sporocysts can be first observed within the mother form by the fourth day of infection, appearing as undifferentiated masses of cells. By the eighth day many are already elongated and motile and by the eighteenth, they begin to migrate towards the distal glandular tissues of the snail where they finally settle and grow. In heavy infections some daughter sporocysts may fail to reach such sites, developing in other parts of the host. A mother sporocyst may give rise to hundreds of daughter forms.

"8. Cercariae arise within the daughter sporocysts by germ ball formation. The first cercarial germ balls may appear while the sporocyst is still on its migratory phase. Once in its final habitat numerous other balls are produced.

Helminthiasis

Vol 45 No 2]

Each one of them elongates after reaching a certain size and develops a constriction at the middle whereby the tail arises. Subsequently, the other organ systems are formed and, in a few days (ca one week), the mature cercaria is ready to emerge from the snail."

" This is a shorter version of the above

OTTOLINA, C. **The Rectoscopic Biopsy by Transparency** A New Diagnostic Method for *Schistosoma mansoni* Amer J Trop Med 1947, Sept, v 27, No 5, 603-6

The author discusses the origin and rationale of the rectoscopic biopsy for the diagnosis of *Schistosoma mansoni* infections described by himself and ATENCIO in 1943 [this Bulletin, 1944, v 41, 945]

In the test, a fragment of mucous and submucous tissue from the upper half of the rectal ampulla is taken from the middle Houston valve about 10 cm from the anus in the area drained by the superior haemorrhoidal veins. This tissue is digested for 3 to 4 hours in 4 per cent caustic potash solution at 60° to 80°C, and examined microscopically after centrifugation.

The author discusses his experience and that of others with the use of this technique, and refers especially to the work of RINCON URDANETA (Rev Policlínica Caracas, 1945, v 14, 325). The value of the rectoscopic method compared with stool and intradermal tests is emphasized and comparative figures from the literature are given. The rectoscopic biopsy is a direct method with only a negative error and thus has an advantage over indirect methods; nevertheless its value would be greater if these false negatives could be avoided.

One factor which seems to influence these errors is that caustic potash digestion, although it made it easier to find eggs in light infections, involved further and harmful manipulation.

Direct microscopic examination of the fragments before digestion did not prove adequate; many devices were tried to make the tissue fragments transparent and eventually it was found that this could be achieved by immersing them for 3 to 5 minutes in fresh water. This dissolves the haemoglobin and the eggs appear in characteristic strings. The living fragment absorbs water quickly and after 3 to 5 minutes becomes a watery globule. This is then compressed between two slides, a drop of water is added, the whole is covered and pressed gently, and a thin transparent film can be seen. The eggs can be easily seen in the film by focussing with the lower power of the microscope at different levels.

The method is simple and rapid and, in light infections, avoids losses which may occur during caustic potash digestion. An important advantage is that normal eggs containing living miracidia are often seen by the transparency method in specimens from untreated patients; such miracidia are killed by the digestion method. This is of therapeutic significance, as it aids in determining the course and results of treatment.

It is stated that the movement of miracidia in individual eggs can be detected with a high power without difficulty, and it is even possible to puncture an egg with a fine needle to deliver the miracidium under microscopic control.

The author concludes by recording that rectoscopic biopsy by transparency presents a clinical diagnosis of *S. mansoni* in a few minutes. The high figures already obtained with the rectoscopic biopsy alone suggest a thorough revision of our clinical knowledge of schistosomiasis. [see also this Bulletin, 1947, v 44, 330]

H J O D Burke-Gaffney

DA SILVA, J. R. & COSTA, N. A biópsia retal no diagnóstico e no controle da eficiência terapêutica da esquistosomíase de Manson. [Rectal Biopsy in the Diagnosis and Therapeutic Control of *Schistosoma mansoni* Infection.] *Hospital* Rio de Janeiro. 1947 Aug v 32, No. 2 219-33 7 figs. [16 refs.] English summary.

The authors found *S. mansoni* eggs in 13 of 100 patients sent for diagnosis of schistosomiasis by the rectal biopsy technique in only 4 of these 13 patients were faecal examinations positive after repeated search. On the other hand, in one patient faecal examination was positive and two biopsies were negative.

The authors refer to the previous work of HERNÁNDEZ MORALES and MALDONADO [this *Bulletin* 1947 v 44 330] and discuss their observations on the possibility of estimating therapeutic efficacy by the morphological study of schistosome ova found in biopsy material.

They conclude that rectal biopsy greatly simplifies the diagnosis of *S. mansoni* infections, especially where laboratory facilities are limited. It is simple, quick, without risk and does not require the detention of the patient in hospital. The paper is illustrated with seven photomicrographs showing ova that were detected. [See OTTOLIXA, above.]

WRIGHT W. H., McMULLEN D. B., BENNETT H. J., BAUMAN P. M. & INGALLS, J. W., Jr. The Epidemiology of Schistosomiasis Japonica in the Philippine Islands and Japan. III. Surveys of Endemic Areas of Schistosomiasis, Japonica in Japan. *Amer. J. Trop. Med.* 1947 July v 27 No. 4 417-47 7 figs.

The authors explain that their report lacks the usual historical review since for various reasons they had not full access to the Japanese literature on the subject. On the other hand, the information collected on the spot from doctors and health workers has been incorporated, and in spite of the language difficulties which were encountered, supplies data not otherwise available in published accounts of schistosomiasis in Japan. The Commission surveyed five known endemic areas of schistosomiasis, with a view to delineating the extent of these areas and gaining information which would assist in the protection of troops stationed in them. "On entering an endemic area, as much information as possible concerning the status of the disease was obtained from prefectural and local health authorities and from practicing physicians. Based on this information, certain schools in various parts of the area were selected, and a representative number of stool samples obtained from children in the higher age groups (8 to 15 years) for macroscopic examination for schistosome eggs. Surveys were then conducted in various parts of the area for *Oncomelania* (*Katayama*) *nosophori*, the snail intermediate host of *Schistosoma japonicum*. When the snails were found, sufficient numbers were collected for transport to the laboratory for examination for incidence of infection.

"All stool examinations conducted by the commission were carried out with the use of the plain sedimentation technique. This technique had previously been found to be the most efficient one for practical use in the field, through research carried out by members of the commission on Leyte and other islands. The technique consisted in taking five grams of feces, stirring the sample in water, straining the material through four layers of surgical gauze into a 250 cc. comcal urinalysis flask, allowing the material to sediment, and pouring off the supernatant fluid. At least three decantations were made. One drop of the final sediment was placed on a slide and examined under the microscope. In the examination of school children in Japan, the commission followed the practice of examining two 22x22 mm. cover glass preparations or one 22x40 mm. cover glass preparation from each sample. A total of 1 688 school

children were examined by the Commission in the five endemic areas, of these, 381 (22.6 per cent) were infected with *S. japonicum*. A higher proportion of males than females were found to be infected, 29.2 per cent of the boys as compared with 16.7 per cent of girls. This finding is in agreement with that of the Japanese who found a preponderance of infection in all cases amongst the male population and ascribed it to "their greater opportunities of acquiring infection."

The following summaries of the Commission's surveys show that the incidence of infection in the human population and in the snail vector varied considerably in the five areas.

(1) *Tone River Area, Chiba and Ibaraki Prefectures*—This has the lowest infection rate of any area in Japan, and only 3 out of 390 school children, examined in six localities, were found to be infected. The Commission was unable to find specimens of *Oncomelania (Katayama) nosophora*, the most important snail vector, although this species of mollusc undoubtedly occurs in some parts of the area.

(2) *The Kofu Area in the Yamanashi Prefecture*—In contrast to the Tone River area, this is the most important schistosomiasis district in Japan, and in spite of the intensive control which has been carried on since 1942, the commission found that 245 out of 458 (53.5 per cent) school children were infected. This figure is more than double that previously recorded in the same school by doctors of the Japanese Health Department, who had estimated that 24.2 per cent of the children were infected. The same Japanese Health Authorities had also examined the general population with the following results—

Results of stool examinations for schistosomiasis carried out in the Kofu area by health authorities of Yamanashi Prefecture between May 1 1944 and April 30 1945

| Area | No Persons Examined | No Persons Positive | Per cent Positive |
|---------------|---------------------|---------------------|-------------------|
| Control | 81 031 | 5 026 | 6.2 |
| Under control | 57 013 | 2,983 | 5.2 |
| Uncontrolled | 22 862 | 2 583 | 11.3 |
| Totals | 160 906 | 10 597 | 6.6 |

That these figures are well below the true infection rate is suggested by the American Commission's comment that "all these examinations were made by means of a single fecal smear with what the commission regarded as inadequate equipment." The evidence obtained from the same source indicates that certain domestic and wild animals are responsible for the transmission of infection to the snail intermediate host.

The snail vector, *O. nosophora*, was found without difficulty in the Kofu Area, and of 200 snails which were crushed and examined, three were found to be infected.

(3) *The Namazu Area in the Shizuoka Prefecture*—Previous data concerning the infection in the general population between 1920 and 1926 were published in 1933, and showed that about 4 per cent of the total population were infected. Since that date, the Japanese have drained a large swamp in the centre of the area and this measure has probably materially reduced the schistosomiasis rate. In the present survey, the American Commission found 14 out of 155 (9 per cent) of the children infected with *S. japonicum*. The snail vector was localized to one area, where, out of 315 *O. nosophora* examined, 2 (0.63 per cent) were infected.

Results of examinations for *S. japonicum* feces lower animals: the tests are carried out by health authorities of Yamaguchi Prefecture between May 1 1944 and April 30 1945

| Species | No. Examined | No. Positive | Per cent. Positive |
|--|--------------|--------------|--------------------|
| Cattle | 7,059 | 2,184 | 30.9 |
| Goats | 1,118 | 158 | 14.1 |
| Dogs | 353 | 178 | 49.9 |
| Horses | 987 | 0 | 0 |
| "Rats" (probably including field mice, <i>Microtus</i> spp.) | 1,707 | 659 | 38.4 |
| Moles | 68 | 13 | 19.1 |
| <i>Muscula</i> sp. | 10 | 9 | 90.0 |

Probably *Muscula (Jukula)* statul.

(4) *The Fukuyama Area in the Hiroshima and Okayama Prefectures.*—Through the organized control work which has been carried on in this area over the past 30 years, the disease has been greatly reduced and the distribution of the small intermediate host considerably restricted. The disease is now confined to the fringes and to the centre of the area, and of 357 children examined from these areas, the Commission found 34 (9.5 per cent.) to be infected. Control measures by the Japanese had considerably reduced the numbers of *O. nosophora* which was now confined to an area of approximately four square miles. Out of 501 snails collected from this area, 19 were found infected, the percentage of infection in the snails collected from different localities varying from 0.5 to 15.8 per cent.

(5) *Kurume Area in the Saga and Fukuoka Prefectures of Kyushu.*—Considerable published Japanese data concerning the previous incidence of schistosomiasis in this area were available to the Commission, but the differences in the techniques employed and in numbers examined made it difficult to compare the results. The Japanese figures depict a steady diminution in the incidence of the disease but the present authors' examination of 328 children from three schools revealed an infection rate of 25.9 per cent., a figure which suggests that there has been little if any decrease in the schistosomiasis infection rate in this area during the past 20 years. The distribution of the snail intermediate host varied considerably *O. nosophora* being found in abundance in the areas with high human incidence of infection, and being absent from, or scanty in, areas with a low human incidence of schistosomiasis. The infection rate among the 510 snails which were dissected varied from 4 to 9.5 per cent. according to the area from which they were collected.

This paper contains references to other helminth infections which were observed in the specimens of faeces examined for the presence of *S. japonicum* on a.

R. M. Gordon

VOGEL, H. & MEYER, W. Ueber die Einwirkung von Brechweinstein, Fuadin und Emetin auf *Bilharzia japonica* und deren Eier im Kaninchenversuch. [The Action in Guinea-pigs of Tartar Emetic, Fuadin and Emetine on *Schistosoma japonicum* and its Eggs.] *Acta Tropica*. Basle. 1947 v. 4 Nos. 1 & 2, 21-56. 97-116. 9 figs. [22 refs.] English summary.

Experiments were carried out on rabbits to ascertain the nature of the effects of certain drugs on the adult *S. japonicum* and whether they would destroy eggs in the tissue of the host.

The animals were exposed to infection with a known number of cercariae, and after the commencement of egg passage 29 of the rabbits were treated with tartar emetic, 7 with foudadin, 10 with emetine and 6 were kept as untreated controls. The dosage was 2.5 mgm (intravenously) for tartar emetic, 0.11 cc (intramuscularly) for foudadin and 2 mgm (intravenously) for emetine. The dosage and intervals between doses was kept constant throughout, but the number of injections varied from 3 to 24.

Tartar emetic—At least 9 to 12 injections were required to cause the eggs to fail to hatch. It was concluded that after 6 injections, about half the adult worms still survived, about one-fifth survived after 12 injections and only about one-tenth after 18 injections. The males were more resistant than the females. Five of 12 animals which had received 15–18 injections, and one of seven animals with 12 injections, were completely cured.

The treatment produced a variety of changes in the adult worms, a marked diminution in size which was proportional to the number of injections, the contents of the intestines were reduced and altered, the testes, ovary and yolk glands were reduced in size and later almost completely destroyed, egg formation was interrupted and then ceased, but one to three months after treatment, the worms which survived recovered their normal appearance and functions.

Foudadin—The effects of this drug on the worms were, in the main, similar to those produced by tartar emetic, but to a lesser degree.

Emetine—With this drug, viable eggs temporarily disappeared from the faeces of some of the treated animals. The worms did not decrease in number in size and the genital organs were unchanged, but the yolk glands reacted by secreting a mass of yolk cells which entered the ovary and caused a clubbed swelling of the uterus, interfering with the functions of these organs. None of the females were unaffected and continued to lay normal eggs. None of the ten animals was cured.

J J C Buckley

RODRÍGUEZ CASTRO, J. Fasciolosis hepática en general, y en especial en España [Infestation by *Fasciola hepatica*, in particular as it occurs in Spain] *Med Colonial* Madrid 1947, Oct 1, v 10, No 4, 221–68, 2 figs & 3 pls [Numerous refs]

The first part of this article need only be mentioned, as the facts related are well known to readers of this *Bulletin*. It deals with a description of *F. hepatica*, its life-history, epidemiology, geographical distribution, intermediate hosts, pathology of infection, treatment and prophylaxis.

The second part, relating to its incidence in Spain, is of more interest and importance from our point of view. It was first reported in sheep by Martín de la Calle in 1890 and in the same year in a workman in Segovia. García Solá's report of a case in 1884 is stated by López-Neyra (in 1933) to have been erroneous, the ova of *Diphylllobothrium* being mistaken for those of *Fasciola hepatica*. Cases are evidently rare. The author mentions one in 1944 in a woman of Almuñécar (the ova were found in the faeces and in the bile), five suspected cases in 1945, of which one was confirmed, another had eosinophilia but no ova were seen in the stools and the use of a duodenal sound was not practicable. In 1946, a third case was proved, a sister of the first in Almuñécar, and soon after one was reported to the author by a doctor who had seen an ovum of *F. hepatica* in the stool of a child suffering from an obstinate diarrhoea. There were evidently others, for the author states that "in 3 years six cases have been seen in Spain." Probably—one might say, certainly—with more thorough examination and more doctors on the look out for cases, the numbers positive would rise, but they cannot as yet be numerous.

differential diagnosis may be perplexing, the author and his colleagues applied the intradermal test with *Dirofilaria immitis* antigen to men who had served in the Pacific.

He discusses the varying results of this test obtained by TALLAFERRRO *et al* [this *Bulletin* 1931 v 28, 214] and SAUNDERS *et al*. [*Ibid.* 1947 v 44 108].

In the present case, 200 men were tested at the U.S. Naval Hospital, Aiea, Oahu, between July 1944 and August 1945. A saline extract of *D. immitis* was used, standardized to contain 0.0005 mgm. of protein per cc. The test was made intracutaneously in the forearm with 0.1 cc. of the solution. No control antigen was used. The results were recorded as Immediate (after 15 minutes and 1 hour) and Delayed (after 24 hours) in terms of 1 plus to 4 plus, according as there was, in the former erythema of from 1 to 4 cm., from that with no weal, up to a weal with pseudopods and, in the latter erythema between 1 and 4 cm. with increasing degrees of subcutaneous oedema.

Results of 2 plus or more were called positive. Of 128 patients with a diagnosis of filariasis, 94 (73 per cent.) were positive of 21 who had lived in Samoa, but who had no evidence of filariasis, 6 (29 per cent.) were positive. In the case of 53 patients who had not been in Samoa or Wallis (and therefore presumably had not been exposed) 10 or 19 per cent. were positive.

In the filariasis group of 64 immediate reactors, 13 were negative at the end of 15 minutes, but positive at the end of an hour. 9 of these were also negative after 24 hours, so they would have been missed if no reading had been taken at 1 hour.

The author notes that SAUNDERS *et al.* (*loc. cit.*) had found 81 per cent. of positive reactors among filariasis patients who had been in Samoa, but only 45 per cent. in those who had not. The present series revealed no such difference but among those not diagnosed as having filariasis, the author found 29 per cent. of positives among those exposed in Samoa, compared with 19 per cent. in those who had not been exposed there. Three positive reactors were found among five patients having *Schistosoma japonicum* infections no positive results were found in four persons suffering from hookworm or in one each suffering from *Acaris Strongyloides* and *E. histolytica*.

The author concludes that while the intradermal test with *D. immitis* antigen is of some diagnostic value for filariasis, it cannot be depended on exclusively as it was negative in 25 per cent. of suspected cases and positive in 19 per cent. of controls.

HARTZ, P. H., HUGENHOLTZ, M. J & VAN DER SAR, A. Helminthia Infection of the Wall of the Gallbladder *Arch. Pathology* 1947 Apr v 43, No. 4 408-11 2 figs. [Refs. in footnotes.]

In the wall of the gall bladder removed from a woman aged 28, a native of Surinam the authors found a necrotic worm in a subserous lymphatic vessel, and eosinophil infiltration. The patient had, some years earlier shown microfilariasis in the blood but schistosomiasis had never been diagnosed. The

worm could not definitely be identified, but it was too large for a larval *Ascaris*, and was probably not a schistosome. The authors think that it was probably a filaria [presumably *Wuchereria*]
Charles Wilcocks

BLOEM, T F, HUYSINGA, J K & WILDERINK, G C [Treatment of Oxyuriasis with Phenothiazine] *Nederl Tijdschr v Geneesk* 1947, July 19, v 91, p 1946 [Summary taken from *J Amer Med Ass* 1947, Nov 8, v 135, No 10, 676]

Bloem and his associates regard phenothiazine as an excellent remedy against oxyuriasis. The patient must be kept under close supervision before, during and after this treatment, and only preparations that have been tested for purity should be used. Hepatic and renal lesions and severe anemia are contraindications to this treatment. As an adjuvant the authors occasionally treated the anal area with a mixture of tumenol, zinc oxide and an anesthetic and prevented constipation. The treatment continues for two consecutive days and is repeated after three weeks. The authors used powders into which 1.25 Gm of phenothiazine had been mixed. Children aged 2 to 4 years were given one powder a day, those 4 to 8 years two powders a day, those 8 to 13 years three powders a day, those 13 to 18 years four powders a day and adults six powders a day. A colorimetric determination of the excreted phenothiazine in the urine is described. One hundred and twenty-three patients were successfully treated. In 1 patient who had been given an overdose of the drug there developed hemolytic anemia.

DEFICIENCY DISEASES

WOODMAN, H M Nutrition of the African in Tsetse-Fly Areas *East African Med J* 1947, Sept, v 24, No 9, 315-36, 1 pl [35 refs]

No scale of recommended dietary allowances has so far omitted meat and milk. Evidence is presented in this paper that these foods can, at least for the race and environment described, in which cattle cannot be kept because of tsetse, be satisfactorily substituted by non-animal foods, and the resulting diet lead to optimum health and development. The paper is modestly described as a "curtain-raiser" to some field nutrition survey work now being undertaken, though qualitative, the observations, conclusions and recommendations will be found to have value far beyond the southern Sudan.

Foods—Meat is only eaten at irregular intervals during a short hunting season. Fish, eggs and milk are rarely if ever used as food. The typical dietary consists of eleusine-manioc flour as a staple, with a wide variety of vegetables, roots, greens and fruit, ground-nuts, beans, oils and other cereals such as maize and rice. (A table of food values of common Sudan foods is given, including some new values.) It might be expected that such a diet would be deficient in high-grade protein, calcium and, seasonally, in vitamin C.

Nutritional Status—The Africans of the southern Sudan are of fine physique, strength and stamina and appear to have a high resistance to endemic diseases such as schistosomiasis and ankylostomiasis. The major deficiency diseases are not found. A few conditions attributable to malnutrition, such as xerosis, phrynoderma and "mosaic skin" are sometimes but not commonly seen, and three diseases, to the causation of which deficiency is probably contributory, are common—namely tropical ulcer, dental caries and leprosy.

Improvements in Nutrition—The author puts forward suggestions for improvement of nutrition as part of a general scheme for raising the standard

of living. The scheme is formulated within the existing framework of social and agricultural customs and food habits. Measures directly concerned with food production include control of shifting cultivation and establishment of families in areas of up to 40 acres each, increased production and improved methods of preserving green vegetables, wider use of the soya bean, the use of food yeast, and the preparation of margarine in areas where vegetable oils are abundant. The author emphasizes, however, that these are only details in a development programme which is mainly economic, social and educational.

Dawn A. Smith

JACQUES J. J. C. Contribution au traitement du "Mbouaki" ou syndrome de dépigmentation du Kwango et du Kasai. [The Treatment of Mbouaki, the Syndrome of Depigmentation, in the Belgian Congo.] *Ann. Soc. Belge de Méd. Trop.* 1947 Mar 31 v 27 No. 1 73-82.

This is the latest of a valuable series of papers from the Belgian Congo on the disease known there as "diboba" or "mbouaki." [See VAN DAELE, this *Bulletin* 1939 v 36 913; PIERAERTS *ibid.* 1943 v 40 408; 1947 v 44 225; DOUCET *ibid.* 1947 v 44 431.] It deals mainly with pathogenesis and treatment, the clinical picture having been adequately described by previous authors.

Treatment was directed primarily against the anaemia, which is one of the outstanding features of the disease. The results are summarized in 0 cases, all infants. All were treated with inorganic iron and anthelmintics. One group in addition received intramuscular injections of liver extract, and another—the largest—was given daily intraperitoneal injections of maternal blood, according to the method described by LODRZYCKI [*Rec. T. Assoc. Sci. Méd. Congo Belge* 1944 no. 2, 157]. In all three groups there was, in most cases, an increase in the haemoglobin level as measured by the Talqvist method. The author makes the important point that the treatment of these patients in hospital may lead to mistaken conclusions about the result and mode of action of therapeutic measures. It is difficult to separate the effect of hospital diet and régime from that of drugs, and this invalidates the conclusions.

As regards pathogenesis, the author concludes that neither intestinal parasites nor malaria play an essential part in causing the disease, although both may aggravate it. The primary cause is a deficiency of protein and an excess of carbohydrate in the diet. In view of the response to iron, there is probably an iron deficiency but vitaminoses are secondary.

[It is of interest that the workers in the Belgian Congo have reached the same conclusions about the cause of this disease as that derived from a study of similar cases many thousands of miles away in the West Indies (WATERLOW this *Bulletin* 1947 v 44 841; *Medical Research Council Spec. Rep. Ser. No. 263* in the press). In both groups of cases protein lack and carbohydrate excess have appeared to be the main causes, with vitamin deficiencies playing a secondary part. The Belgian writers have laid much stress on anaemia, which is not prominent in the West Indian cases. The latter however do not suffer from either malaria or intestinal parasites. This supports Dr Jacques' view that these conditions are not of primary importance.] J. C. Waterlow

PASSMORE R. Mixed Deficiency Diseases in India: a Clinical Description. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1947 Oct., v 41 No. 2, 189-208. [37 refs.]

It has been pointed out by TROWELL (this *Bulletin* 1946, v 43, 1062) that the classical deficiency diseases are rare in Africa, whereas the effects of inadequate food intake are widespread. The same is true of India—beriberi, fœtid pellagra,

scurvy and rickets are seldom seen, but a symptom complex caused by varying degrees of mixed deficiency of total calories, protein, A and B-complex vitamins, and complicated by protozoal and helminthic infestations is distressingly common

Though brief reference is made in this paper to the probable causation of individual manifestations by individual nutritional deficiencies, it is mainly devoted to a description of the over-all clinical picture seen in the common multiple deficiency state. There may be wide variation among individuals, the effects of one deficiency predominating or one system being mostly affected, but there is discernible in all cases a basic pattern which is substantially the same as that seen in Africa and other parts of the world

General—Loss of weight and listlessness are prominent early features. A profound depression and lack of the will to live may prove a serious obstacle in treatment

The Skin—Superficial hyperkeratosis with atrophy of the sebaceous and sweat glands produces a skin which is dry, rough and scaly, and which has a crazy pavement appearance. Tropical ulcer is often associated with these changes, but the part played by nutrition in its aetiology is still uncertain. There is frequently involvement of the hair follicles, which gives rise to the distinct and characteristic follicular hyperkeratosis. Angular stomatitis, cheilosis and lesions of all muco-cutaneous junctions are attributed mainly to riboflavin deficiency

The Eyes—Xerophthalmia, keratomalacia and Bitot's spots with impaired dark adaptation (mainly avitaminosis A) are probably the commonest signs of malnutrition in India. Superficial keratitis and nutritional amblyopia are common only in the south

The Digestive System—In most cases of malnutrition, glossitis and diarrhoea are present, the latter being the principal cause of death. General atrophy of the whole intestinal tract is usually seen at post-mortem examinations. Liver function in cases of malnutrition has been little investigated in India; in fatal cases, the liver is usually small and invariably fatty

The Cardiovascular System—There is usually evidence of cardiac atrophy with hypotension. Anaemia is usual, with some degree of macrocytosis but the haematological picture is variable and probably represents the combined effects of nutritional deficiency and chronic malaria

Treatment—To secure a right psychological attitude and active co-operation is the first essential. This involves a cheerful ward, willing staff, attractive food and a certain pandering to the patients' whims. Milk is the standby in most cases. Vitamin preparations are of use in individual symptom-groups, but rarely achieve complete cure. Yeast products are of value, especially in out-patient work. The necessity for adequate treatment of co-existing infections and infestations is emphasized

Two printing errors have slipped in; their presence in no way diminishes the value of this excellent paper. On page 201 'the value of vitamin A (anurin) therapy' (next paragraph) Vitamin B₁ (thiamine) has been should obviously read 'the value of Vitamin A therapy'. Vitamin B₁ (thiamine or anurin) has been. And the paragraph heading on page 203 'Treatment of Carcinoma Infections' should presumably read 'Treatment of Concurrent Infections'.

Dear A. Sinha

BRADY W. R. Malnutrition of the Nervous System *Brit Med J* 1947, Nov 15 70(34), 41, 2nd ed's.

It has recently become increasingly apparent, that a number of neurologic diseases are related to defects of diet or defective absorption of essential

nutrients. This relationship was the subject of a discussion at the Neurological Section of the International Congress of Medicine in September 1947 when this was the introductory paper.

As befits an opening paper it deals with the problems in general and slightly provocative terms. It uses as examples chiefly the neuropathies recorded in prison camps during the second world war.

In the main the discussion centres on the question: Intoxication or deficiency? and the difficulty of this apparently simple distinction is well exemplified in the cases of beriberi and arsenical poisoning. In the former which is due basically to a dietary vitamin deficiency the tissues may well be damaged by products of imperfect intermediary metabolism, in fact by local intoxication whereas in the latter it has been shown that arsenite interferes with the pyruvate enzyme system and in arsenical poisoning the damage may be, in effect, due to local enzyme deficiency.

On somewhat parallel lines are discussed the aetiology of pellagra, Wernicke's encephalopathy, painful feet, the captivity cord syndromes and captivity cranial nerve lesions.

DEAN A. SMITH

NICHOLLS L. Thiamine of Milled Raw and Parboiled Rices. [Correspondence] *Nature*. 1947 Aug. 30 298.

It is known that a large part of the thiamin of wheat, rye, maize and barley is in the scutellum of the grain (39 per cent. of all the thiamin of wheat is in the scutellum) and it is probable that the same is true of rice. It has usually been assumed that when rice is parboiled, some of the thiamin is distributed from the germ into the whole grain, and that subsequent milling and removal of the germ does not therefore completely eliminate the thiamin. Nicholls, however, has examined milled parboiled rice grains and compared them with milled raw rice grains and concludes that the effect of parboiling is rather to make the scutellum more adherent so that in subsequent milling only part of it is removed, and therefore part of the thiamin is retained. With raw rice the whole germ is removed. Parboiling may cause some distribution of the thiamin throughout the grain, but its chief effect is probably retention of the scutellum.

CHARLES WILCOCKS

SPRUE

BLACK, D. A. H. & SIMPSON, J. A. Serum Lipides in Tropical Sprue. *Tr. Roy Soc. Trop. Med. & Hyg.* 1947 Oct. 41 \ 2, 741-54 [12 refs.]

Estimations of total fatty acid, lipide phosphorus and cholesterol were estimated in the serum of 18 patients suffering from tropical sprue and of 9 normal persons. These were repeated at intervals after a standard meal containing 18 gm. of fat. The fasting level of total fatty acid in sprue did not differ significantly from normal values, but phospholipide and cholesterol were significantly lower. After a fatty meal, the total of fatty acids increased less in sprue patients than in normal persons, but phospholipides showed a smaller increment than did neutral fatty acid. The cholesterol usually fell in sprue patients. No significant change was demonstrated in the fat curve after a period of liver treatment in four patients.

This low fat curve in sprue fits in well with the more direct evidence of faulty fat absorption given by stool analyses. The observed changes can be

well explained on the basis of STANNUS's hypothesis [this *Bulletin*, 1943, v 40, 259] that the absorption defect affects only those lipides which are phosphorylated during absorption, but they cannot be said to prove it

P Manson-Bahr

ELDER, H H A **Clinical Features, Diagnosis, and Treatment of Sprue** *J Trop Med & Hyg* 1947, Nov, v 50, No 11, 212-18

Four hundred cases of sprue were investigated and treated, all were in British soldiers. A table giving the place of origin shows that 75 per cent arose in Bengal, Assam or Burma. This is shown below —

| | |
|---|-----|
| Bengal, Assam and Burma | 306 |
| W India | 44 |
| S India and Ceylon | 27 |
| Central, North, North-West India and Overseas | 23 |

The highest seasonal incidence in India, Assam and Burma was in May, June and July

Long residence is not essential, as the following table suggests —

| | |
|------------------------------|----------------------|
| Residence of 6 months-1 year | 37 (9.25 per cent) |
| „ 1-2 years | 147 (36.75 per cent) |
| „ 2-3 years | 171 (42.75 per cent) |
| „ Over 3 years | 45 (11.25 per cent) |

Descriptions are given of the various clinical manifestations. For fat analyses, the patients were given, for three days, a diet containing about 23 gm of fat, and a typical specimen of each stool passed during the three days was collected. An analysis was made of the mixture.

In 40 per cent of cases, the total faecal fat was within normal limits, and it was shown that fully established sprue can persist in the absence of steatorrhoea. In a control analysis on the stools of 10 healthy men under the same conditions, the mean total faecal-fat was 29.3 per cent of the dried stool, the maximum being 34.4 per cent. Out of the total —

| | |
|-----------------------------------|-----|
| Glossitis was present in | 393 |
| Stomatitis was present in | 212 |
| Angular stomatitis was present in | 177 |
| Cheilitis was present in | 62 |

The diagnosis and prognosis of the disease are discussed.

In treatment, sulphaguanidine (given in the acute stage) with an initial dose of 7 gm and then 3.5 gm every four hours up to a total of 60 to 70 gm checked the diarrhoea and caused a marked improvement in the general condition. Liver was used in the treatment of anaemia and vitamin preparations for local lesions, with variable results.

Detailed clinical notes of four cases are given. Four diet schedules are set out in an appendix.

P Manson-Bahr

WEIR, J F & COMFORT, M W **Folic Acid Therapy in Nontropical Sprue: Results of Treatment in Seven Cases** *J Lab & Clin Med* 1947, Oct, v 32, No 10, 1231-41

These seven cases have been worked out in great detail, and no useful purpose can be served by summarizing all the data.

Control data were collected before institution of treatment, and special attention was paid to the frequency, duration and severity of the exacerbations, including frequency and character of stools. Haematological studies included

sternal puncture. The concentration of calcium phosphorus, total protein, albumin and globulin in the serum, as well as values for phosphatase and prothrombin times, were determined. X-ray examination of the skull, hands and teeth for osteoporosis, as well as of the small bowel for the so-called deficiency pattern, was secured. In four subjects the faecal solids, fats and nitrogen were determined daily during a three-day test period.

Vitamins, including sufficient vitamin K to control hypoprothrombinaemia, were given. The dosage of folic acid usually was 50 mgm. daily by the intramuscular route.

Treatment with folic acid did not result in improvement in the sense of well-being, gain in weight or strength that could not be equally well accounted for by increased intake of food, and natural remission of the disease. Frequency or severity of exacerbation of the intestinal manifestations did not change. Moreover the haematological response was disappointing. All these points are in marked contrast to the favourable responses of tropical sprue to folic acid. Whether the two conditions are different, or whether these cases had advanced to an irreversible stage is impossible to state. P. Manson-Baker

HAEMATOLOGY

FINDLAY G. M., BOULTER, E. A. & MACGINNON C. B. A Note on Sickness and Flying. *J. Roy. Army Med. Corps.* 1947 Sept. v 89 No. 3 138-41

Experiments were carried out in West Africa to determine whether a flight up to 15 000 feet above sea level, without administration of oxygen, would induce an acute haemolytic crisis in Africans with sicklaemia.

Three Africans with sicklaemia showed no ill-effects from such a flight although all showed the presence of sickled red cells at 15 000 feet above sea level after ten to fifteen minutes at this height.

"Differences in the rate at which sickling occurred; *in vitro* in different individuals were noted and are correlated with the *in vivo* findings.

BERNARD PINTO, H., CARBONELL, L., GIL, J. A. & GÓMEZ, O. L. Primera descripción de la anemia drepanocítica en Venezuela. [First Record of Sickle-Cellled Anemia in Venezuela.] *Rev. Politécnica Caracas.* 1947 Jan. Feb. 16, No. 82, 1-29, 7 figs. [15 refs.]

A very detailed report of case.

EPIDEMIC DROPSY

MITRA, H. & RAO K. K. P. N. Investigations into an Outbreak of Epidemic Dropsy. *J. Indian Med. Ass.* 1947 June, v 16 No. 9 303-6.

The authors were called upon to investigate a sudden outbreak of bowel complaints associated with swelling of the extremities. [No dates or names of places affected are stated, so the report is deprived of much of its value as a historical record.] Four hundred and fifty-eight persons were affected out of a total of 794 the adults being railway employees. The diagnosis rested between beriberi and epidemic dropsy. None of the patients was under

8 months of age, the percentage of infected rose from 17 (8 out of 47) below two years of age, to 65.7 (136 out of 207) adult females and 75.5 (173 out of 229) adult males. Investigation traced the source to mustard oil purchased at the railway provision store. As some time had elapsed since the start of the outbreak, only nine samples of the mustard oil could be collected. Six of these gave the Argemone oil reaction of LAL and his colleagues. The symptoms were typical. Abdominal pain and discomfort, flatulence, diarrhoea for 3-5 days, occasionally more, followed by swelling of the legs. In a few patients the swelling of legs preceded the diarrhoea. Palpitation and shortness of breath were also complained of. The interval between obtaining the oil and the onset of symptoms ranged between 9.3 and 15.6 days, with an average of 11.3. The outbreak died down rapidly when issue of the oil from the store was stopped.

DERMATOLOGY AND FUNGUS DISEASES

KERVAN, P & ARETAS, R. Deux cas d'histoplasmosis observés au Soudan français [Two Cases of Histoplasmosis seen in the French Sudan] *Bull Soc Path Exot* 1947, v 40, Nos 7/8, 270-76 [11 refs]

[The two cases described in this paper are the same as those noted in this *Bulletin*, 1947, v 44, 1018. These cases, and two cases of histoplasmosis from tropical Africa identified by the reviewer in 1943 and 1946 respectively—the only authentic cases of the disease so far reported from this part of the world—all showed the larger form of *H capsulatum* in the lesions.]

J T Duncan

EMMONS, C W, BELL, J A & OLSON, B J. Naturally occurring Histoplasmosis in *Mus musculus* and *Rattus norvegicus* *Pub Health Rep Wash* 1947, Nov 14, v 62, No 46, 1642-6 [14 refs]

In a previous paper [this *Bulletin*, 1947, v 44, 848], the authors reported the discovery of histoplasmosis in a house mouse (*Mus musculus*) during an investigation on the occurrence of the disease in an area of Loudoun County, Virginia. The present paper deals with the continuation of this investigation and records the discovery of histoplasmosis in 10 wild rats (*Rattus norvegicus*) trapped on three different farms. It is noteworthy that the infected animals showed no macroscopic sign of the infection and they were detected only by cultivation of *Histoplasma capsulatum* from their tissues, chiefly the liver and spleen. This, the first recorded discovery of naturally acquired histoplasmosis in wild rodents, constitutes a very important advance in the elucidation of the puzzling epidemiology of the disease, albeit the infection is not known to be transmitted directly from animal host to animal host.

Additional observations were the discovery of *Blastomyces lanuginosa* in one mouse, and a species of *Cryptococcus*, pathogenic for experimental animals, which was isolated from 81 animals, chiefly rats and mice.

HEAT STROKE AND ALLIED CONDITIONS

MARRIOTT H. L. Water and Salt Depletion. *Brit. Med. J.* 1947 Feb. 15 Mar 8 & 15 45-50 285-90 & 328-32, 10 figs. [122 refs.]

(The Croonian Lectures delivered at the Royal College of Physicians, London December 1946)

Water and salt are perhaps the most important substances it is in our power to administer in a wide variety of clinical conditions. They can be so used as to achieve seeming miracles or so misused as to lead to avoidable fatalities. The effects of water and salt depletion have commonly been confused recent experimental and clinical work have made it possible to recognise with certainty the separate effects and to treat them on sound physiological lines.

In the present paper the author presents a lucid and immensely valuable summary of the whole subject.

Among the important physiological considerations vital to the understanding of water and salt depletion are —

(1) The distribution of body fluid between the intracellular (about 35 litres in an adult man) and extracellular (about 14 litres) compartments.

(2) The subdivision of the latter into plasma (about 3 litres) and tissue or interstitial fluid (about 11 litres) and the constant to-and fro filtration which occurs between them, governed by hydrostatic pressure and by the colloid osmotic pressure of the plasma protein.

(3) The necessity for maintaining osmotic isotonicity of the tissue fluid as the internal environment of cells, distribution of water between cellular and tissue fluids being determined by the osmotic pressure of electrolyte ions.

(4) Renal regulation of extracellular fluid osmotic pressure by selective reabsorption of components of the glomerular filtrate.

(5) The magnitude of the daily "unavoidable" loss of water by vaporization (lungs and skin, 1 000 ml.) and as the minimum urine volume for excretion of waste products (500 ml.)

Pure water depletion occurs when water intake stops or is greatly diminished and when there is no significant sodium chloride loss in secretions. It may be caused by deprivation of water as in shipwreck, or by inability to swallow as in severe dysphagia, great weakness or coma. The extracellular fluid becomes hypertonic because water is lost without parallel salt loss, water is sucked from the cells, extracellular fluid volume tends to be maintained and dehydration is principally cellular.

Pure salt depletion occurs when there are abnormal losses of sodium and chloride in the presence of adequate water intake. It may arise in severe vomiting or diarrhoea from any cause continuous gastro-intestinal suction drainage biliary or intestinal fistulae Addison's disease or most characteristically in heat exhaustion (severe sweating accompanied by free drinking of unsalted fluids). The osmotic pressure of the extracellular fluid falls and the kidneys excrete water to maintain its isotonicity. This leads to diminution of extracellular fluid volume—secondary dehydration. There follows the condition of oligæmic circulatory failure or shock and death is due to decreased blood volume and increased blood viscosity. There may be, as a secondary effect, disturbance of the acid-base balance when there is asymmetrical loss of sodium or chloride ions, e.g. alkalosis in severe vomiting and acidosis in diarrhoea (as in cholera).

The effects of water and salt depletion are compared in the following table —

| Manifestation | Pure Water Depletion | Pure Salt Depletion |
|----------------------|---------------------------------|---|
| Dehydration | +++ primary or simple | +++ secondary or extra-cellular |
| Thirst | +++ | Absent |
| Lassitude | + | +++ |
| Orthostatic fainting | Absent till late | +++ |
| Urine volume | Scanty | Normal till late |
| NaCl in urine | Often + | Always absent (except in Addison's disease) |
| Vomiting | Absent | May be +++ |
| Cramps | Absent | May be +++ |
| Plasma NaCl | Slight increase or normal | Greatly decreased |
| Blood urea | + | +++ |
| Plasma volume | Normal till late | Greatly decreased |
| Haemoconcentration | Not till late and slight | +++ |
| Blood viscosity | Normal till late | Increased +++ |
| Blood pressure | Normal till late | Fall +++ |
| Water absorption | Rapid | Slow |
| Mode of death | due to rise of osmotic pressure | Peripheral circulatory failure |

Adequate treatment depends not only upon an accurate qualitative diagnosis, but on an estimate of the quantitative extent of the deficiency in terms of deficit of water or of isotonic saline, either may be as high as 10 litres. In this connexion and in control of treatment the simple and rapid method of FANTUS (*J Amer Med Ass*, 1936, v 107, 14) for estimating chloride in urine is invaluable (details of technique and interpretation are given and may also be found in this *Bulletin*, 1944, v 41, 74)

Treatment—In water depletion, water should be given by mouth or per rectum unless circumstances compel parenteral administration, in which case isotonic glucose solution (5 per cent) is the best vehicle for the water. In salt depletion, isotonic saline solution should be used until symptoms are relieved or until chloride reappears in the urine, when it should be replaced by hypotonic ($\frac{1}{2}$ to $\frac{1}{3}$ isotonic) saline. The aim should, in either case, be to achieve a minimum urine volume (in an adult) of 1 pint per 8 hours with a salt content of 3 to 5 gm per litre.

An adult suffering from any significant degree of either water or salt depletion will need to receive within the first 24 hours at least a gallon ($4\frac{1}{2}$ litres) of appropriate fluid

Dean A. Smith

TROPICAL ULCER

GUTCH, C F Local Penicillin Therapy for Tropical Ulcer *U S Nav Med Bull* 1947, Sept-Oct, v 47, No 5, 801-4, 1 fig

The author estimated that about half of the Chinese coolies in a camp in Szechwan Province suffered from tropical ulcer. The hygienic conditions of the coolies were bad, undernourishment was rife, malaria and tuberculosis were common and parasitism was almost invariably present.

The ulcers were readily differentiated and they followed in general the classical descriptions, with spirochaetes, fusiform organisms and secondary

bacteria. The usual lengthy series of treatments were tried with varying degrees of success, but it is noted that local applications of sulphamamide powder produced some measure of success in several cases. Initial therapy consisted of cleansing the affected limb with soap and water irrigation of the ulcer with hydrogen peroxide and saline, and removal of as much necrotic tissue as possible.

Owing to inadequate response of the ulcers to other forms of treatment, local penicillin was applied to some of them after initial cleansing. Dry penicillin sodium (100 000 to 200 000 units) was sprinkled over the surface, which was then covered with gauze impregnated with vaseline this confined the concentrated solution of penicillin (the penicillin dissolved rapidly in the serum of the wound) to the area having most organisms. The patients were seen daily and further applications of penicillin were made if necessary.

In 32 of 35 ulcers so treated, granulation tissue assumed a healthy appearance and peripheral induration diminished significantly in 24 to 72 hours. When the wound became clean it was kept so with sulphamamide powder and dry dressings. In the three more resistant cases, similar results were achieved after 5 to 8 days treatment with penicillin. Most of the patients experienced a local burning after the application this disappeared in a few minutes, and was the only ill-effect noted.

Details are given of one case in which satisfactory results with penicillin, followed by sulphamamide were obtained, so that on the 10th day "pinch" grafts could be placed on the granulations. The patient had been working throughout the treatment and continued to do so despite ambulation, all the grafts took and within three weeks thereafter epithelialization was complete. [See also this *Bulletin* 1948 v 43, 958 *ibid* 1947 v 44 748, 935]

H J O'D Burke-Gaffney

MISCELLANEOUS DISEASES

MACCREARY D & BRICKER, A. G. The Incidence of Intestinal Parasites among Civilians employed at certain Naval Air Bases. *U.S. Nav. Med. Bull.* 1947 Sept.-Oct., v 47 No. 5 928-9.

When Parnamarim Field, Natal, Brazil was being surveyed for anti-malarial purposes in 1943 the authors noted that latrine facilities for the hundreds of native labourers were lacking and that heavy faecal pollution of the neighbouring scrub brush was taking place.

Many stools showed evidence of diarrhoea and a preliminary examination of direct smears from 15 fresh stools produced startling results nine species of intestinal parasites were found, each sample contained at least one species and one contained no less than six. Seven of the fifteen showed *E. histolytica*. The full results are shown in a table.

Examinations were therefore made of waiters and dish washers. Similar stool examinations were made at Pici Field, Fortaleza, some 200 miles to the north of Natal, and at Aratu seaplane base and Ipitanga Field, both within 25 miles of Bahia and approximately 30 miles apart, and some 450 miles to the south of Natal.

A total of 133 examinations are recorded from Natal (61) Fortaleza (44) Aratu (15) and Ipitanga (13).

Although only one stool was obtained from each person and no concentration methods were used, not one parasite-free sample was obtained.

Among other findings revealed in a table are that hookworm had the highest incidence, accounting for 71 per cent for the whole group (although Aratu seaplane base produced 93 per cent of *Ascaris*) *Ascaris* accounted for 62 per cent for the whole group *E histolytica* varied from none at Ipitanga to 27 per cent at Fortaleza and *E coli* averaged 37 per cent *Strongyloides* occurred in 13 per cent and the other common parasites in lesser degree

Schistosoma mansoni was found once at Fortaleza, twice at Aratu and three times at Ipitanga it was not found at Natal, where conditions appear to be unfavourable for *Planorbis*

The authors note the difficulties in avoiding the ingestion of parasites in such an area and the need for rigid precautions to avoid contamination of food and water Despite the small series, the investigation does represent a segment of conditions in four areas extending some 850 miles along the coast Although unusual care was taken, one of the authors acquired *E histolytica* and *Ascaris* infections it is observed that long intervals without fresh vegetables will cause a normally cautious person to "take a chance" H J O'D Burke-Gaffney

DAVIES, J N P Pathology of Central African Natives Mulago Hospital Post Mortem Studies Series III *East African Med J* 1947, Aug, v 24, No 8, 289-303 [26 refs]

Lobar pneumonia has long been recognized as accounting for a high proportion of deaths amongst Africans VINT, in Nairobi, [*East African Med J*, 1928, v 5, 383] found it responsible for death in 42 per cent of post mortems he performed in one year, and in 1937 [*ibid*, v 13, 332] reported finding the disease in 29.8 per cent of 1,000 consecutive autopsies, the right lung being predominately affected GARNHAM and DE SMIDT [*ibid*, 1931, v 8, 150], typing pneumococci from 100 cases in Africans, found Type IV in 91 per cent, ORMISTON in England (1942) found this type in England in 61 per cent

In 2,994 autopsies performed at Mulago, Uganda, lobar pneumonia was found in 15.7 per cent, more persons dying from this condition than any other Bacteriological examination of 170 cases showed pneumococci in 90 per cent, but right lung involvement was not nearly so marked as in Nairobi There is no evidence that the disease is more severe than in England, possibly it is even milder Most of the deaths appear to have occurred in the third decade of life

Of the 472 cases recorded 37 per cent showed complications due to the infection (*cf* VINT, 1937 *loc cit*, who reported 26.2 per cent in Nairobi). These were as follows —

| | | |
|---------|---|-------------------------|
| Group 1 | Local complications in the lungs | 43 cases (9.1 per cent) |
| I | Suppurative softening (small abscesses) | 3 cases (0.6 per cent) |
| II | Abscess | 33 cases (6.9 per cent) |
| III | Gangrene of lung (all lower lobe) | 8 cases (1.7 per cent) |
| IV | Delayed resolution and carnification | 15 cases (3.1 per cent) |

Group 2 Direct spread from lung

Only one case of subphrenic abscess and one of suppurative mediastinitis were noted Empyemata were found in 43 instances (9.1 per cent) and of 14 cases examined bacteriologically, pneumococci were found in 13, staphylococci in one Pericarditis occurred in 39 (8.1 per cent), 23 being purulent, there was no evidence that this was usually associated with right lung involvement In only 2 per cent of the empyema cases were there septicaemic complications

Group 3 Septicaemic complications

Meningitis 16 (3.3 per cent), 12 of 13 cases were pneumococcal and 1 meningococcal

Endocarditis 15 (31 per cent.) 9 out of 10 cases examined being pneumococcal and 1 due to *Haemophilus influenzae*. Septicaemic signs without localization were found in 4 cases. One interesting complication was pneumococcal encephalitis—recognized in 12 cases. At autopsy lobar pneumonia was found, the meninges being slightly hyperaemic but without exudate and with sterile cultures the brain was hyperaemic and in some cases large punctate haemorrhages were found. Portions of the brain removed and injected intracerebrally into animals failed to show a virus but the animals died of pneumococcal meningitis. Peritonitis was found in 8 cases.

The above figures are analysed and compared with those of Oiler & Macrae, and Vint in a table in the text.

Of 253 cases of broncho-pneumonia 40 were apparently primary 26 secondary to enteric fever 35 showed marked malnutrition 40 had syphilis and 29 tuberculous 22 cases occurred in children. Malnutrition and gross structural changes e.g. cirrhosis of the liver are considered to play an important predisposing part in pneumonia, the so-called "tropical diseases" a relatively unimportant one.

The question whether pyogenic infections are more common in Africans than in Europeans requires further surveys but some differences are apparent. Firstly streptococcal infections in Africans are relatively rare and harmless (at any rate in Kampala) this is not the case in Europeans (the reviewer has found the Masai living mostly on blood milk and meat to have a high apparent degree of immunity to this infection.) The pneumococcus shows a greater tendency in Africans to cause septicaemia without lung involvement.

What evidence there is available suggests that the incidence of lobar pneumonia is high in Africans but here it must be remembered that the records come mostly from people herded together in towns industrial areas etc., i.e. away from their normal environment and that the disease is most common in newcomers. The probability is that in his normal habitat the African acquires immunity only to those types common in his district. The theory that blockage of the reticulo-endothelial system is responsible for the frequency of septicaemia is hard to accept and it is difficult to see what infections are to blame the spleen of many Africans is fibrosed (because of malaria) but much of the reticulo-endothelial tissue lies outside this organ.

It is thought that increased susceptibility to septicaemic and pyogenic disease lies mainly in two causes.

(1) Malnutrition (very common) (2) Poor economic conditions, & severe labour. Liability to constant abrasions and ulcerations of the skin poor housing, exposure to cold and wet all give more opportunity to infection than in Europeans.

[It is a truism to say that more than half the problem of improving the general health of the African lies in better feeding especially with proteins of high biological value.] [For Parts I and II of this series see this Bulletin 1947 v 44 1098.]

PROTOZOOLOGY GENERAL

SPENA, A. Contributo allo studio della toxoplasmosi e considerazioni sulle diverse specie che costituiscono il genere *Toxoplasma*. [Species of *Toxoplasma*.] *Riv di Parasit.* Rome. 1947 June Sept. v 8, Nos. 2/3, 85-104 6 figs. [19 refs.] English summary (3 lines).

Toxoplasmosis was observed in laboratory guinea-pigs in Addis Ababa. The infection was inoculable from guinea-pig to guinea-pig, as also to the rabbit and

a calf The parasites occurred in all the organs The author discusses the identity of the parasite in relation to *Toroplasma caviae* Carini and Mighano, 1916, and concludes that it is better to consider that a single species exists which would be *T gondii* Nicolle and Manceaux, 1919 C M Wenyon

ENTOMOLOGY AND INSECTICIDES GENERAL

KAHN, M C Females Mosquito "Calls" and their possible Significance in Control *Kuba Habana* 1947, May, v 3, No 5, 119-20

In this short article the author describes how he made recordings of the sounds produced by the females of the following mosquitoes *Anopheles quadrimaculatus*, *Aedes aegypti*, *Aedes albopictus* and *Culex pipiens* The records were made in a sound-proof chamber kept at atmospheric conditions comparable with those in the natural environments of the insects He states that "most of the significant sounds are made while the insects are at rest" and are in the range of from 200 to 8,000 cycles per second The recordings are not audible to the human ear, they "require to be amplified some one-hundred million times or more" He claims, however, that an experienced observer can distinguish the sounds of one genus or species from another and can also distinguish the sounds made by the sexes of the same species When a record of a female voice is played, males of the same species fly towards it, the author therefore hopes to transfer the sounds to magnetic tape for continuous playing and to test its ability to lure males to an electrical device which will kill them [See also this *Bulletin*, 1945, v 42, 661] H S Lenson

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

BARRETT, R H Health Regulations for Air Travel *Brit Med J* 1947, Nov 8, 741-3 [Summary appears also in *Bulletin of Hygiene*]

The rapidity of air transport at the present time has greatly increased the difficulties of health authorities throughout the world in view of the lack of clinical signs of infectious disease to be expected among the passengers examined It is necessary therefore, to place more reliance on immunization, and hence it is insisted that vaccines of known efficiency should be used and that the passenger should produce proof, in the form of certificates, that the operation has been performed satisfactorily

The author has discussed briefly the methods of control and the regulations in force against the five major epidemic diseases, yellow fever, smallpox, cholera, plague and typhus

In Table I are listed the accepted incubation periods of these diseases, and the periods of validity of the certificates of immunization agreed on internationally

TABLE I

| Disease | Incubation Periods | Periods of Validity of Certificates of Immunization |
|--------------|--------------------|---|
| Yellow fever | 6 (India) 9 days | For 10 days to 4 years from date of inoculation |
| Smallpox | 14 days | For 14 days to 3 years from date of vaccination |
| Cholera | 5 days | For 6 days to 6 months from date of inoculation |
| Plague | 6 days | Not stated, but usually for 6 months from date of inoculation |
| Typhus | 12 days | For 1 year from date of completion of course of inoculations |

Inoculation and Vaccination.—The number of inoculations or vaccinations required by a particular passenger depends on the route on which he will fly. It will be necessary for him to comply with the regulations of each country in which he lands as well as those of the country of departure and of his destination. The regulations however usually make a distinction for a passenger who is only in transit through a country and not disembarking into it, and in the former case an alleviation of the rules is sometimes permitted. Health authorities are naturally anxious to prevent the entry of a person incubating any disease into a country where conditions are particularly favourable for its spread. This is the case in India, where regulations against the importation of yellow fever are very stringent in consequence of the presence of *Aedes* mosquitoes. Similarly, in Australia, special precautions against smallpox are insisted on.

Variation in Validity of Immunization Certificates.—The periods of validity of certificates of inoculation and vaccination as shown in Table II vary in certain countries and it is necessary to ensure that each passenger is in possession of certificates that are valid for all countries in which he will land during his journey. It would, of course, simplify the procedure for passengers if all countries would agree to accept the same periods of validity.

TABLE II

| Disease | Convention Validity | Limits of Variation | |
|--------------|---------------------|------------------------------|------------------------------|
| | | Maximum | Minimum |
| Yellow fever | 10 days/4 years | 15 days/2-4 years (India) | 15 days/2 years (Madagascar) |
| Smallpox | 14 days/3 years | 21 days/2 years (Egypt) | 12 days/1 year (Thailand) |
| Cholera | 6 days/6 months | 14 days/6 months (Abyssinia) | 6 days/3 months (Hong Kong) |
| Plague | None stated | 5 days/3 years (Cyprus) | 6 days/3 months (Hong Kong) |
| Typhus | —/1 year | 12 days/1 year (Lebanon) | 8 days/6 months (Cyprus) |
| Typhoid | None stated | 6 days/1 year (Burma) | 6 days/3 months (J. va) |

*Calculated from date of completion of inoculation or of vaccination.

It is important that the passenger and practitioner should take into account the interval of time that must elapse before the certificates of these operations become valid. These periods are referred to in Tables I and II. The

consequences to a passenger who is not in possession of the requisite certificates may be a refusal of permission to embark, an enforced period of quarantine at the port of disembarkation, or refusal of permission to land

In general, vaccination against smallpox and inoculation against the typhoid group should be recommended to any person proceeding abroad. Other inoculations need be advised only when epidemics are known to be in progress.

If the methods employed to control the entry of disease into countries by air appear to assume an importance not hitherto known in sea or land transport, it should be remembered that practically all international flights are, from the point of view of quarantine, well within the incubation period of the major epidemic diseases.

All materials for these inoculations, except yellow fever vaccine, are available for use by practitioners. The yellow fever vaccine must be kept under more exact conditions and so is only available for inoculation in certain centres which are listed.

A brief description of health regulations affecting aircraft and crew is also given
F O MacCallum

WORTHINGTON, E B *A Development Plan for Uganda* With a Foreword by His Excellency the Governor of Uganda, Sir J. Hathorn. HALL pp. xii+112, 10 figs (8 maps) 1946 Dec. Entebbe Govt Press [Shs 2/50]

At the present time there is a strong movement to develop the economic and social life of the countries of Africa, and a growing realization that if this is not undertaken thoroughly, and soon, the people will shortly be faced with famine because their agricultural habits are not adequate to keep pace with a rapidly increasing population. At the same time there is the realization that although much is known about the economic potentialities of these countries, much remains to be discovered before any rational plan of progress is possible. The present volume is the outcome of a study of the problems inherent in any scheme of development. Dr Worthington's wide knowledge and experience have enabled him to correlate the different sides of the subject, and to formulate proposals.

He discusses the matter under various headings —The fundamental problem, finance, the productive services, social services, the common services, and special developments. The chief and most stubborn fact of the fundamental problem is that the present population of about 4,000,000 is likely to increase to 10,000,000 in the next 50 years, and that the productive capacity of the soil will then be used to its fullest extent, if all suitable land is made available. At present the land is not all available, but much more could be worked if, for instance, lack of water was made good. The country could support this enlarged population if the output per person were increased, and if the large areas now unused were rendered usable.

This plan cannot satisfactorily be summarized, and readers are referred to the original for details of the many enquiries made and opinions expressed. The author has received much assistance from those who have worked in Uganda, and studied its problems, for many years.
Charles Wilcocks

KALRA, S L *Addu Atoll (Maldivé Islands) Its People and its Important Diseases* *J Indian Army Med Corps* 1947, July, v 3, No 3, 137-41

The Maldivé Islands are atolls, rising no more than a few feet above sea level, the soil is mainly soft coral sand, rich in lime. Vegetation is abundant, and palms, plantains, breadfruit, papayas, sweet potatoes and other bulbous roots grow prolifically, the growth of scrub is very thick. Swamps, some of sweet water, abound, and fresh water is easily obtained from shallow wells. The

average rainfall is 68 inches per annum. The author describes the conditions of life which have already been recorded by MARSON (this Bulletin, 1943, v. 43, 1202)

The common diseases are scrub typhus, malaria, filariasis and dysentery. The only *Anopheles* is *A. tessellatus* which breeds solely in wells of fresh water. It has been found infested in nature. The range of flight of *A. tessellatus* is more than half a mile but less than two miles. In wells containing small fish (*Barbus* spp.) no mosquito larvae could be found. Spleen rates are fairly high. Culicine mosquitoes are abundant.

Scrub typhus is probably carried by *Trombicula delaisi* in these islands; the local people are apparently immune and cases have been found only in the garrison. Filariasis is due to *Wuchereria bancrofti* and both *Culex fatigans* and *C. asturus* have been found infected. Filariasis is present in all villages.

Ulcers of the legs, due to secondary infection of injuries from coral, are fairly common.

Charles W. Wilcocks

PEARSE, A. S. [Edited by]. *Zoological Names. A List of Phyla, Classes, and Orders.* Prepared for Section F American Association for the Advancement of Science. 22 pp. 1947. Durham, North Carolina.

A second edition of this list which was first issued in 1936 and which has been out of print for several years, has now been published. In this, a number of corrections have been made. The list does not go beyond suborders.

In his preface to the first edition the editor discusses some of the difficulties attending any effort to achieve uniformity in zoological nomenclature, and admits that he has been unable to do so. He names the large number of experts who have advised him on the nomenclature adopted in the various sections. Two columns are given on each page the first comprising the names (with authors and dates) which the editor after consultation believes to be in best current usage the second containing the names which a few zoologists would like to see used. The following endings are adopted—Phylum and Subphylum, -a Class, -ea Subclass, -ia Order, -ida Suborder, -ina.

This is a most useful reference list, which will help zoological teachers and students (including medical men interested in tropical diseases) to avoid some of the confusion which now exists in zoological nomenclature.

Charles W. Wilcocks

BOOK REVIEW

BLACKIE W. H. (M.D., Ph.D. F.R.C.P. (Ed.) D.T.M. & H. Hon. Consulting Physician, Salisbury Hospital, Southern Rhodesia, etc.) *Malaria, with special reference to the African Forms.* 101 pp. 44 coloured figs. on 1 pl. 1947. Cape Town. Published for the Post-Graduate Press by the African Bookman. [10s. 6d.]

This monograph on malaria is the first book to be published for the Post Graduate Press of Cape Town with the aid of a grant from Messrs. Bayer Pharma Ltd. It is written from the point of view of the general practitioner and specially for those working in Africa. It is for the latter reason that the book has a particular value. None of the standard text-books on tropical medicine, nor the earlier monographs on malaria, gives quite such a clear

picture of those forms of the disease encountered in tropical and Southern Africa. No one has yet demonstrated the exact nature of the differences that exist between African and classical malaria and the author makes no claim to have done so, though he takes the generally accepted view that strains of parasites and the degree of immunity in the indigenous population are important factors. He also points out that the high order of premunity prevailing among the adult population calls for a very different approach to the diagnosis of any acute fever.

The book comprises a clear account of the parasitology and pathology of malaria, the clinical features and treatment. It is confined to human forms of the disease, and it does not include within its scope a description of the anopheline vectors, epidemiology, or of measures of control. There is a coloured plate which gives an adequate picture of the various species of malarial parasites, though it omits the degree of magnification and the method of staining, and it includes *Plasmodium tenue*, a parasite which is not mentioned in the text.

The author adopts the unusual clinical classification into the following forms —

In Europeans

- 1 Acute benign malaria—due to *P vivax*, *P ovale* or *P malariae*
- 2 Acute malignant malaria—due to *P falciparum*
- 3 Chronic malaria

In Africans

- 1 Acute malaria—due to any species
- 2 Chronic malaria

This classification may be of value to the practitioner, but it leads to some overlapping in the description of the clinical features, and its use must tend to the ignoring of species diagnosis which is the only rational approach. A more serious defect is the division into European and African forms of the disease—the division should be into susceptible races and relatively non-susceptible races. Many Africans (i.e., adult Africans) come into the former category and their disease syndromes are identical with those of Europeans. A proper understanding of this problem can only be reached after prolonged study of the nature of immunity and this, unfortunately, is dealt with very sketchily. A book which is written with special reference to the African forms surely deserves more than a page and a half on this subject.

A full account is given of the clinical features and of the different pernicious forms of *P falciparum* malaria. Blackwater fever is not included in this monograph. Some of the statements which echo from text-book to text-book are again repeated here: their accuracy is doubtful and their importance is magnified. To begin with, this emphasis on the protean manifestations of the disease is very little justified. Ross [above, p. 141] has recently pointed out the dangerous error of regarding malaria in this way, in the vast majority of cases it is a simple illness easily recognized, and diagnosed for certain by finding parasites in the blood. Again, how valid are all these different forms of pernicious malaria: algid, hemiplegic, bulbar, hyperpyrexial, gastric dysenteric, pneumonic, sudoral etc? How often are these in reality meningococcal meningitis, a virus encephalitis, a bacillary dysentery, heat stroke etc? Lastly may be mentioned the statement that is so often read and for which there is so little evidence, that the infant mortality from malaria amongst African children is heavy. As Sir Leonard Rogers (*Fevers in the Tropics*) has pointed out, when such deaths are more closely investigated, the true figure gets lower and lower (e.g., from 90 per cent to 20 per cent).

In the chapter on diagnosis, the author recommends the use of Giemsa's stain and of Field's rapid method. It is an advantage to become complete master of one or two methods—nevertheless a description of Leishman's stain might have been added, and the J.S.B. rapid stain (this *Bulletin* 1944 v 41 822) is superior in many ways to Field's. It is strange to find sternal puncture included in aids to diagnosis whilst the much more useful—and therapeutically valuable—method of adrenaline provocation (of Ascoli) is omitted.

In regard to treatment both curative and prophylactic, the author recommends the current standard procedures. He takes a commonsense view on the use of injections. If the patient cannot absorb the drug by the oral route, then parenteral administration is necessary. In one place, the author gives the curative dosage of mepacrine as 0.3 gm. a day (p. 81) in another 0.3 gm. thrice daily (p. 83) apparently he means the former. All the dosages recommended are perhaps slightly on the high side (e.g. quinine 30 grains daily for approximately 5 days, followed by 0.3 gm. mepacrine daily for 5 days). Not many patients would consent to stay in bed for 3 or 4 days after the temperature has become normal. The author follows the lead of Marchiafava and other Italian physicians in stressing the importance of lumbar puncture in the therapeutics of cerebral malaria.

The danger of becoming over-enthusiastic in regard to a new form of treatment is well illustrated in this book, in the case of paludrine. Fortunately the author had time to insert an addendum, stating that this drug fails to bring about the rapid control of African fevers as claimed in the original publications and that severe attacks of malignant malaria have occurred in spite of systematic paludrine prophylaxis.

The book as a whole is full of interest, is well presented and contains few mistakes. The above criticisms of the reviewer are largely on matters of opinion on a subject which is so prone to dogmatism. Genuine mistakes do occur—for instance—the statement that the "various members of the genus (*Plasmodia*)" (p. 9) develop in the female *Anopheles* mosquito—instead of in various genera of mosquitoes. Matters of opinion are illustrated by assertions such as "hepatic tenderness is almost invariably present" (p. 40) in acute malaria. This is perhaps true in Southern Rhodesia where the author works, but it may not be so in other parts of Africa. The statement that "wherever Europeans live in an area of endemic malaria it is clearly necessary to supplement all other prophylactic procedures by means of chemoprophylaxis" would probably now be accepted by only a minority of tropical workers.

TROPICAL DISEASES BULLETIN

Vol 45]

1948

[No 3

SUMMARY OF RECENT ABSTRACTS*

III MALARIA ,

Epidemiology

STEVENS and BLACKMAN (p 169) report malaria in two persons, living in Oxford, who had never been out of Britain, and LEVICK and MACGREGOR (p 789) refer to two cases of malaria in London children, which were probably contracted in Welling and the Isle of Sheppey respectively FERMONT (p 874) also records a case of malaria in a patient who had no previous history of malaria and who had lived for some years in England, but she had lived in the tropics until 1937

VOGT (p 172) reports a case of malaria apparently contracted in Norway, in which the incubation period was probably 8-9 months HERNBERG (p 951) states that *P vivax* malaria, which had been almost absent from Finland for 20 years, was found in Finnish troops during the recent war, and in civilians The source was, apparently, the Russian troops, and most cases were related to Karelia In many cases the incubation period lasted 9 months The same author (p 15) discusses the long incubation period (which may be up to one year) observed in the malaria of Finland, basing his opinions on findings during an epidemic in troops in 1944-45

Indigenous malaria in Vienna has apparently increased in recent years WENGER (p 951) attributes this largely to the number of infected persons who have returned from war service

PUTNAM and HACKETT (p 15) report on malaria in Sardinia during 1925-34, where *A maculipennis labranchiae* and *A sacharovi* are the vectors The density of anophelines and the prevalence of malaria declined sharply in one area after limited control measures had been instituted in 1925

ALOSI (p 155) shows that during the war there was a marked increase of malaria in Sicily, partly because the people were dispersed as a result of bombardment, and partly because new strains of parasites were introduced by the troops

KOUSSITASSEFF (p 638) describes the declining incidence of malaria in Bulgaria, where *A maculipennis*, *A superpictus* and *A sacharovi* are the vectors He ascribes the decline to the antimalaria measures taken, but does not give details

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947 v 44 References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed

BERLEMSCHIEV (p. 636) discusses in detail the possible effects of large-scale migrations of population or of troops, in relation to malaria, and considers these possibilities in the light of actual happenings in Russia during the war. The abstract should be read in full.

SANJUAN FUENTES (p. 486) discusses malaria in the Tangier Zone, where *P. vivax* is the predominant parasite.

WILSON (p. 952) sums up the malaria experience of the troops in Madagascar where *P. falciparum* is the common parasite. Malaria is hyperendemic in parts with high spleen and parasite rates in children. *A. gambiae* is present throughout the island, and is a serious vector but *A. funestus* is the chief carrier in the higher country.

TURNER and WALTON (p. 640) have compiled a detailed report on malaria in Freetown, where the chief vectors are *A. gambiae* and *A. nedei*. Transmission is perennial, with great exacerbation during the rainy season, and mosquitoes are often blown out to ships in harbour even as far as two miles from the shore. Although the general sanitary level of the town is low the malaria position has improved since the beginning of the century and during the war the various precautions taken in military units reduced the risk from a probable rate of 1,000 per 1,000 to 73 per 1,000 per annum. At the present time, *P. falciparum* is the predominant parasite.

SCHWETZ (p. 786) finds that the limit of altitude for endemic malaria in the Belgian Congo is about 1 750 metres above sea level.

MATILLA *et al.* (p. 279) report on the spleen rates found in the island of Fernando Po.

COVILL (p. 797) discusses the whole question of the effect of irrigation on malaria in India. The most dangerous form of irrigation is by perennial canal, and the chief sources of danger arise from general raising of the subsoil water level, seepages and leakages. The solution of this serious problem lies in cooperation between the engineer and the malarologist. RAO and NAMURUDOM (p. 16) show how the construction of a dam across a river in Mysore, and of a canal fed from the reservoir thus formed, raised the level of subsoil water practically to ground level, and created conditions in which *A. culicifacies* bred and caused an epidemic of malaria in an area previously fairly healthy which was followed by conditions of hyperendemicity. An enormous multiplication of snails also took place with the result that fluke disease of sheep and cattle caused great loss. In part of Madras a large irrigation scheme is proposed, which involves construction of a large dam, and a large lake. In a preliminary survey of the area, RAO *et al.* (p. 952) found endemic malaria in only 68 of 312 villages, but epidemics occur after seasons of abnormal rainfall. *A. culicifacies* is the chief vector but *A. stephensi* also plays a part.

DE BURECA (p. 853) gives an account of malaria at Fort Sandeman in the north-east of Baluchistan, where *A. culicifacies* and *A. stephensi* are the commonest anophelines. There is evidence that these were caught 3-3½ miles from their breeding places.

HARPER and his colleagues (p. 953) have written a series of comprehensive papers on malaria in the U.S. forces in the South Pacific, where it caused casualties five times as numerous as those due to combat. In the most severe epidemics the incidence was at rates up to 2,678 per 1,000 per annum, but mosquito control and suppression by drugs greatly reduced the incidence. The authors think that *A. farauti* (which they regard as a species rather than a variety of *A. punctulatus*) is probably the only important vector in the South Pacific after most of the other anophelines even *A. punctulatus*, are zoophilic in habit. MACKERRAS and ARNDSEN (p. 535) report a malaria survey at Wewak, New Guinea. The vector is *A. punctulatus farauti* and transmission is probably perennial. Spleen rates and parasite rates and counts are high.

in infancy, and fall in childhood, as does the gametocyte count. The picture is one of hyperendemicity with development of immunity. It is likely that infants provide the sole source of infection of anophelines with *P. falciparum*, since the gametocyte counts in older children and adults are probably too low for effective transmission.

WATSON and RICE (p 35) show that in the Tennessee Valley, negroes suffered less illness from malaria than white persons, but blood examination showed that they had a greater relative number of infections. The negroes lived under similar, or worse, conditions than the white people.

MONTESTRUC (p 641) reports on malaria (largely due to *P. falciparum*) in Martinique, where it is found only on the south coast, and where the incidence is not heavy. BELLERIVE and DAMBREVILLE (p 16) discuss malaria in Haiti, where it is an important problem.

BATISTA (p 875) records malaria (chiefly due to *P. vivax*) as he saw it at a hospital in Amazonas, Brazil.

Aetiology

In a discussion of the generally accepted nomenclature of the malaria parasites of man, CHRISTOPHERS (p 158) argues that although these names are incorrect, according to the rules of nomenclature, to alter them would lead to such confusion that the rules should, in this connexion, be suspended. SABROSKY (p 556) makes a contribution to the question of nomenclature of malaria parasites, which should be read in the original.

In *Federation Proceedings* (p 400) there is a series of papers on the biochemistry of malaria parasites, in which much of the work done in recent years is summed up. This cannot successfully be condensed.

DAVEY (p 954) discusses the question of exoerythrocytic schizogony in human malaria, the evidence that it takes place is indirect, but strong. LANZA (p 160), however, thinks that no satisfactory evidence has yet been found of exoerythrocytic forms of malaria parasites in man, and discusses the various appearances of cells and parasites which are likely to be mistaken for these forms. OBERLÉ (p 159) describes what he considers to be exoerythrocytic forms of *P. vivax* in man, after infection by inoculation of infective blood in 5 patients with general paralysis. In comment, WENYON refers to the fact that merozoites are extra-cellular, and contain no pigment, for part of their cycle, but that they may be taken up by phagocytes and may even undergo some development in them before being destroyed.

FONSECA *et al* (p 487) have studied the infection of chick embryos with *P. gallinaceum*, and the formation of exoerythrocytic stages of the parasite. They have also examined bone-marrow and blood in human infections with *P. vivax* and *P. falciparum*, and they think that there is a reticulo-endothelial phase, preceding the erythrocytic phase, in human as in avian malaria, though they admit that complete proof has not been found. In comment, WENYON gives the opinion that some of the forms described by these authors may be merozoites from erythrocytic schizogony rather than true exoerythrocytic forms.

DUBIN (p 955) describes bodies which suggested exoerythrocytic forms of *P. vivax* in tissue cultures.

DEANE (p 17) shows that the chromatin of *P. vivax* and *P. knowlesi* stains well by the Feulgen technique provided that the slide has previously been exposed to alkaline alcohol, she discusses the reason for this.

SHUTE (p 18) describes the Madagascar strain of *P. vivax* maintained for 22 years in the Horton hospital, and transmitted since 1933 by a strain of *A. maculipennis* raised from a single female.

FERREBEE and GEIMAN (p 17) have devised a centrifugation method for separating infected from non-infected red blood cells, this depends on mixing

together equal volumes of heparinized infected blood and albumin solution of specific gravity 1071

FERRAZZI *et al.* (p. 17) have conducted a study by injecting radio-active iron, from which they conclude that *P. vivax* tends to invade young red blood cells. BELTRÁN and SANDOVAL (p. 160) show that merozoites of *P. vivax* exhibit a preference for reticulocytes.

BLACK (p. 18) has cultivated *P. falciparum* and *P. vivax* *in vitro* and notes that they grow as well in serum from a malaria patient as in normal serum. He describes the stages observed, noting that cells invaded by *P. falciparum* tend to clump and adhere to any leucocytes present, and that *P. vivax* prefers young red blood cells.

MOSEMOVSKI (p. 956) shows that there is a linear relationship for *P. vivax* and *P. falciparum* between temperature and rate of development in the mosquito. The threshold for development of the latter is higher than that of *P. vivax*.

SMOLINSKAJA (p. 875) found *P. falciparum* in various stages of schizogony in venous blood when finger blood, and sternal and spleen puncture material, contained only ring forms. He thinks, therefore, that the peripheral regions of the venous system might represent the normal sites of schizogony of *P. falciparum*.

SOVINEV (p. 878) has found that the strain of *P. ovale* originally isolated in the Soviet Union, has retained its characteristics during many years of use in the treatment of general paralysis. LISOVA *et al.* (p. 876) have infected various anophelines with this strain but an editorial comment relating to their work suggests that it may not be true *P. ovale*.

BASU (p. 1030) shows the frequency of distribution of gametocytes of the three common species, in a series of gametocyte carriers in India.

T. TRANSMISSION

Investigating the entry of hungry *A. maculipennis atroparvus* into human or animal houses, VAN TRIEL and WEURMAN (p. 557) conclude that atmospheric conditions are much less important than the odour of pig or man, in attracting the mosquitoes. They (p. 787) have found experimental evidence to indicate that *A. maculipennis atroparvus* is attracted by CO₂ in the atmosphere up to a concentration of 10 per cent.

ETHERINGTON *et al.* (p. 163) quote evidence which indicates that *A. hyrcanus* and *A. maculipennis mesasiatica* usually considered to be of no malaria importance in Italy do in fact transmit in part of the Po valley. It seems probable that these mosquitoes picked up infection from patients with general paralysis treated by malaria therapy in a hospital in which mosquito screening had fallen into disrepair.

ULITCHOVA (p. 162) shows that in Uzbekistan the breeding of anophelines takes place chiefly in swamps during spring and chiefly in rice-fields during summer. PLITNEV (p. 957) names the anophelines found in southern Kazakhstan where malaria is common and VELTISHCHEV (p. 957) those found near Kazalinsk in the same area. Breeding places are described by both these authors. IVANOVA (p. 483) points out that anopheline larvae are capable of crawling over moist surfaces when escaping from a drying pool in search of water. He has studied their reactions to light under these circumstances. USTIKOV (p. 491) has studied the gonotrophic cycles of *A. maculipennis* in the Caucasus—details should be sought in the original abstract.

UNGUREANU (p. 557) describes certain morphological features of females of *A. maculipennis* which greatly assist in the differentiation of adults of the various races. AKALIN (p. 163) reports morphological anomalies in male genitalia of *A. maculipennis*.

ETHERINGTON and SELICK (p 19) record their observations on *A. sacharovi* in Persia and Iraq, where it is commonly associated with spleen rates between 60 and 100 per cent. *A. superpictus* and *A. maculipennis maculipennis* are also found.

USTINOV (p 490) points out that *A. claviger (bifurcatus)* is the commonest mosquito on the Black Sea coast of the Caucasus, and that its larvae develop through the winter, reaching stage IV by March.

KRIVONOSOVA (p 161) and IVANOVA (p 161) discuss the breeding of *A. plumbeus* in tree-holes.

In a comprehensive report, TREDRE (p 488) describes the breeding habits of *A. melas* in the *Paspalum* grass and *Avicennia* mangrove areas of tidal marshes in the neighbourhood of Freetown, Sierra Leone. Breeding is maximal soon after the onset of the rains, but as these become heavy, the rate declines, to rise again as the rains diminish. Infection has been found in up to 4.7 per cent. The author discusses identification by characters of the adult and of the egg. THOMSON (p 795) gives an account of *A. melas* and *A. gambiae* in West Africa. In transmission the latter is nearly three times as effective as *A. melas* and together, these mosquitoes form a very formidable partnership. *A. melas* breeds in *Avicennia* mangrove near Freetown, but round Lagos and in the Gold Coast it is associated with the great stretches of *Paspalum* grass in the inter-tidal zone. It makes use of fresh water only to a negligible extent, and is therefore confined to the area below high spring-tide mark. THOMSON (p 795) comments on the breeding habits of *A. gambiae* in West Africa, which are not understood. It breeds in streams and in some pools and puddles, but by no means all, and the conditions which render one pool suitable and another not, are not clear. *A. gambiae* remains the most dangerous malaria vector in the world.

JEPSON *et al* (p 1030) describe the habits of *A. funestus* and *A. gambiae*, the two vectors of malaria in Mauritius, the former is the more important, because it can breed in colder conditions, and throughout the year, whereas *A. gambiae* is restricted to the hot wet season. *A. gambiae* tolerates a high degree of salinity along the coast, but the true *A. melas* has not been found there. *A. funestus* does not tolerate more than a trace of salt. The effect of shade is to reduce breeding of *A. funestus*, but this is probably due to reduction of temperature rather than to the effect of light.

VINCKE (p 163) found a sporozoite index of 7 per cent in *A. duren* caught in the Belgian Congo. This mosquito was not found in houses or stables but formed a high proportion of the anophelines caught in the open.

WOLFS (p 164) describes 9 species of *Anopheles* caught near Coquilhatville, of which *A. moucheti* is probably the most important local vector, endemic malaria is relatively light in this area.

Senior WHITE (p 787) discusses the outside resting places of certain Indian anophelines. It seems that a high proportion are to be found outside at a period of the gonotrophic cycle when it is usually assumed that they are at their feeding sites and therefore susceptible to spray-killing with pyrethrum insecticide. The same author (p 797) sums up the relationship between ricefields and the breeding of *Anopheles* in India. Where *A. annularis* is the vector, all ricefields are dangerous for *A. culicifacies* the danger period is until the plant is 12 inches high, for the *A. fluviatilis* group all non-seepage ricefields are harmless, but seeping ricefields are very dangerous. Fallow fields are also very dangerous in relation to *A. culicifacies* and the *A. fluviatilis* group.

RAJINDAR PAL (p 19) shows that in Delhi the optimum conditions for *A. culicifacies* are temperature of 25°-30°C, and relative humidity from 60 to 80 per cent. This species does not hibernate or aestivate and is not here a habitual feeder on man, it does not usually fly more than half a mile from its

together equal volumes of heparinized infected blood and albumin solution of specific gravity 1071

FERRAZZ *et al.* (p. 17) have conducted a study by injecting radio-actin serum, from which they conclude that *P. vivax* tends to invade young red blood cells. BELTRÁN and SANDOVAL (p. 100) show that merozoites of *P. vivax* exhibit a preference for reticulocytes.

BLACK (p. 18) has cultivated *P. falciparum* and *P. vivax* *in vitro* and notes that they grow as well in serum from a malaria patient as in normal serum. He describes the stages observed, noting that cells invaded by *P. falciparum* tend to clump and adhere to any leucocytes present, and that *P. vivax* prefers young red blood cells.

MOSEHOVSKI (p. 956) shows that there is a linear relationship, for *P. vivax* and *P. falciparum* between temperature and rate of development in the mosquito. The threshold for development of the latter is higher than that of *P. vivax*.

SMOLYNSKAJA (p. 873) found *P. falciparum* in various stages of schizogony in venous blood when finger blood, and sternal and spleen puncture material, contained only ring forms. He thinks, therefore, that the peripheral regions of the venous system might represent the normal sites of schizogony of *P. falciparum*.

SOFFIYEV (p. 875) has found that the strain of *P. ovale* originally isolated in the Soviet Union, has retained its characteristics during many years of use in the treatment of general paralysis. LISOVA *et al.* (p. 876) have infected various anophelines with this strain, but an editorial comment relating to their work suggests that it may not be true *P. ovale*.

BAHU (p. 1030) shows the frequency of distribution of gametocytes of the three common species in a series of gametocyte carriers in India.

TRANSMISSION

Investigating the entry of hungry *A. maculipennis atroparvus* into human or animal houses, VAN THIEL and WEURMAN (p. 557) conclude that atmospheric conditions are much less important than the odour of pig or man in attracting the mosquitoes. They (p. 787) have found experimental evidence to indicate that *A. maculipennis atroparvus* is attracted by CO₂ in the atmosphere, up to concentration of 10 per cent.

ETTERINGTON *et al.* (p. 163) quote evidence which indicates that *A. byrsonae* and *A. maculipennis messiae* usually considered to be of no malaria importance in Italy do in fact transmit in part of the Po valley. It seems probable that these mosquitoes picked up infection from patients with general paralysis treated by malaria therapy in a hospital in which mosquito screening had fallen into disrepair.

ULITSKYA (p. 162) shows that in Uzbekistan the breeding of anophelines takes place chiefly in swamps during spring and chiefly in rice-fields during summer. PLETNEV (p. 957) names the anophelines found in southern Kazakhstan where malaria is common and VELITSCHIEV (p. 857) those found near Kazalinsk in the same area. Breeding places are described by both these authors. IVANOVA (p. 488) points out that anopheline larvae are capable of crawling over moist surfaces when escaping from a drying pool in search of water. He has studied their reactions to light under these circumstances. USTIAOV (p. 491) has studied the gonotrophic cycles of *A. maculipennis* in the Caucasus—details should be sought in the original abstract.

UNGUREANU (p. 557) describes certain morphological features of females of *A. maculipennis* which greatly assist in the differentiation of adults of the various races. AKALIN (p. 163) reports morphological anomalies in male genitalia of *A. maculipennis*.

ETHERINGTON and SELICK (p 19) record their observations on *A. sacharovi* in Persia and Iraq, where it is commonly associated with spleen rates between 10 and 100 per cent. *A. superpictus* and *A. maculipennis maculipennis* are also found.

USTINOV (p 490) points out that *A. claviger (bifurcatus)* is the commonest mosquito on the Black Sea coast of the Caucasus, and that its larvae develop through the winter, reaching stage IV by March.

KRIVONOSOVA (p 161) and IVANOVA (p 161) discuss the breeding of *A. plumbeus* in tree-holes.

In a comprehensive report, TREDRE (p 488) describes the breeding habits of *A. melas* in the *Paspalum* grass and *Avicennia* mangrove areas of tidal marshes in the neighbourhood of Freetown, Sierra Leone. Breeding is maximal soon after the onset of the rains, but as these become heavy, the rate declines, to rise again as the rains diminish. Infection has been found in up to 4.7 per cent. The author discusses identification by characters of the adult and of the egg. THOMSON (p 795) gives an account of *A. melas* and *A. gambiae* in West Africa. In transmission the latter is nearly three times as effective as *A. melas*, and together these mosquitoes form a very formidable partnership. *A. melas* breeds in *Avicennia* mangrove near Freetown, but round Lagos and in the Gold Coast it is associated with the great stretches of *Paspalum* grass in the inter-tidal zone. It makes use of fresh water only to a negligible extent, and is therefore confined to the area below high spring-tide mark. THOMSON (p 795) comments on the breeding habits of *A. gambiae* in West Africa, which are not understood. It breeds in streams and in some pools and puddles, but by no means all, and the conditions which render one pool suitable and another not, are not clear. *A. gambiae* remains the most dangerous malaria vector in the world.

JEPSON *et al* (p 1030) describe the habits of *A. funestus* and *A. gambiae*, the two vectors of malaria in Mauritius. The former is the more important, because it can breed in colder conditions, and throughout the year, whereas *A. gambiae* is restricted to the hot wet season. *A. gambiae* tolerates a high degree of salinity along the coast but the true *A. melas* has not been found there. *A. funestus* does not tolerate more than a trace of salt. The effect of shade is to reduce breeding of *A. funestus*, but this is probably due to reduction of temperature rather than to the effect of light.

VINCKE (p 163) found a sporozoite index of 7 per cent in *A. durem* caught in the Belgian Congo. This mosquito was not found in houses or stables, but formed a high proportion of the anophelines caught in the open.

WOLFS (p 164) describes 9 species of *Anopheles* caught near Coquilhatville, of which *A. moucheti* is probably the most important local vector, endemic malaria is relatively light in this area.

Senior WHITE (p 787) discusses the outside resting places of certain Indian anophelines, it seems that a high proportion are to be found outside at a period of the gonotrophic cycle when it is usually assumed that they are at their feeding sites and therefore susceptible to spray-killing with pyrethrum insecticide. The same author (p 797) sums up the relationship between ricefields and the breeding of *Anopheles* in India. Where *A. annularis* is the vector, all ricefields are dangerous for *A. culicifacies* the danger period is until the plant is 12 inches high for the *A. fluviatilis* group, all non-seepage ricefields are harmless but seeping ricefields are very dangerous. Fallow fields are also very dangerous in relation to *A. culicifacies* and the *A. fluviatilis* group.

RAJINDAR PAL (p 19) shows that in Delhi the optimum conditions for *A. culicifacies* are temperature of 25°-30°C, and relative humidity from 60 to 80 per cent. This species does not hibernate or aestivate and is not here a habitual feeder on man, it does not usually fly more than half a mile from its

breeding place. No morphological differences could be found between specimens caught in areas where *A. culicifacies* is, and those where it is not, a vector.

Senior WHITE and RAO (p. 491) show that *A. annularis* widely spread throughout the East but usually not of much malaria importance is the chief vector in the plains of Orissa, where it finds favourable breeding conditions in village tanks with a heavy growth of aquatic vegetation, and in ricefields during the rains. It can be controlled by attention to the tanks. *A. senilis* breeds in salty waters on the low-lying coast and is a more dangerous vector than *A. annularis*.

VISWANATHAN (p. 391) describes the relationship between seasonal rainfall, irrigation systems, and the breeding of *A. flaviatilis* in part of Bombay—this mosquito is responsible for transmission in the rice and sugar-cane areas. *A. flaviatilis* was the only species found infected in one area of the Southern Central Provinces of India by Senior WHITE (p. 656).

Senior WHITE *et al.* (p. 37) show that *A. flaviatilis*, *A. vexans* and *A. minimus* are the chief vectors of malaria in the Jeypore Hills, and have calculated the anthropophilic indices of these and others. They found also that a high proportion of some species survived more than 12 days in the cold weather.

SIMPSON (p. 663) discusses the transmission of malaria by *A. stephensi* in Calcutta, where this species formed 87 per cent. of *Anopheles* caught in houses, and where its total infection rate was 0.85 per cent.

From an analysis of the results of a large trapping experiment in Burma, YORK and FOX (p. 160) conclude that *A. minimus* is attracted by man, and hardly at all by animals, whereas *A. acutus* and *A. philippinensis* are almost entirely animal feeders.

Until recently it had been assumed that the vector of malaria in North Borneo was *A. maculatus* but an investigation made by McARTHUR (p. 788) showed that this assumption could not explain the peculiar distribution of the disease. By careful research, the author was led to suspect *A. leucosphyrus* and this was, in fact, the only anopheline found infected in the area surveyed, although many other species were present. *A. leucosphyrus* breeds in clear seepages under dense jungle shade, and the female visits houses after midnight, and departs after feeding without resting. Control by partial clearing of the jungle, to admit light, gives promise of success.

PERRY (p. 391) reports careful studies of *A. punctulatus farauti*, the chief vector in the New Hebrides and Solomon Islands. It breeds in many kinds of water always open to the sun—eggs may be laid on mud, and they and the larvae and pupae can withstand partial drying. Details should be sought in the original.

MACKERRAS (p. 642) gives a list of Australasian vectors. The dangerous vectors are *A. punctulatus punctulatus* and *A. p. farauti* [the latter being regarded as a race of *A. punctulatus*]. For the list of potential vectors and those of unknown importance the abstract should be consulted.

YOUNG *et al.* (pp. 275-482) have shown that several North American anophelines including *A. quadrimaculatus* are able to transmit *P. wexleyi* from various other parts of the world. YOUNG and BURGESS (p. 694) have succeeded in transmitting *P. malariae* by *A. maculipennis freeborni*.

A list of anophelines caught during a special survey in Canada is given by TWINN (p. 664)—the known vectors, *A. quadrimaculatus* and *A. maculipennis freeborni* were found in various provinces.

ATKIN (p. 663) has given a full account of the anopheline fauna of western America, but this cannot be condensed.

PAYFOUND *et al.* (p. 21) have studied the close relationship between the amount of aquatic or semi-aquatic vegetation and the breeding of *A. quadrimaculatus*. Methods of water management suitable for the control of over 100 plants are

discussed, the most difficult being the alligator weed, which produces a floating mat, and which needs larvicidal oil. The flowering of certain plants gives a readily recognizable indication of the beginning of the anopheline breeding season. GARTRELL and ORGIN (p 20) note that *A. quadrimaculatus* tended to disperse relatively far from a reservoir on the Tennessee in which it was breeding prolifically. BROOKE and PROSKE (p 22) have prepared a serum by intraperitoneal injection of macerated pupae of *A. quadrimaculatus* into a rabbit. A precipitin test with this serum may be of value in the study of natural enemies of mosquitoes. HUNT and DAVEY (p 694) describe in detail their method of maintaining a colony of *A. quadrimaculatus*. SABROSKY *et al* (p 392) report infection in 3.38 per cent of *A. crucians* in S Carolina, this mosquito is usually considered of relatively slight importance. It feeds actively in November, when *A. quadrimaculatus* is hibernating. FITZGERALD (p 274) reports on malaria in a US naval base in Cuba, where *A. albimanus* is the vector. VARGAS (p 959) reports *A. darlingi* in part of Mexico in which it had not previously been found.

In a study of Brazilian anophelines, DEANE, CAUSEY and DEANE (p 20) have shown that the most efficient indigenous vector is *A. darlingi*, and that *A. aquasalis* becomes important if very numerous. *A. albicans* (which may include a number of species) and *A. pessoai* are of secondary importance. Morphological information, and keys, are included in the original papers. PAYNE and SANCHES (p 692) note that *A. darlingi* is the most important vector in the remote areas of Brazil, and FLOCH (p 486) that it is the most important vector in French Guiana, where the maximum incidence occurs in the dry season, and where most of the cases are due to *P. falciparum*. SCHIAVI (p 165) shows that *A. albicans domesticus* is the commonest anopheline, and probably the most important vector, at Iguape, on the coast of Brazil, where endemic malaria is severe. CASTILLO (p 276) notes that in Ecuador *A. albimanus*, *A. darlingi* and *A. pseudopunctipennis rivadeneirai* are important vectors. HACKETT (p 276) shows that *A. pseudopunctipennis* which is responsible for much malaria in the Andes, exists up to altitudes of 2,600 metres, he notes that it is probably not a homogeneous species, but consists of several varieties. RACHOU (p 165) reports on the habits of anophelines of the sub-genus *Kerteszia* in part of Brazil, where they show a strong tendency to invade houses. RACHOU and FERREIRA (p 1032) have studied the anophelines (of the sub-genus *Kerteszia*) which breed in bromeliads, in southern Brazil. RACHOU (p 1032) has found infection in *A. cruzi*, *A. bellator* and (probably) *A. homunculus*, of this group.

Pathology Clinical Findings

In a comprehensive discussion of the cellular basis for immunity in malaria, TALIAFERRO (p 493) describes the fixed and free macrophages, noting that one effect of acquired immunity is an increased rate of phagocytosis, the local increase in the macrophages is probably a reflection of natural immunity. He discusses the proliferation of various tissues which occurs in malaria. This paper cannot satisfactorily be abstracted. SPRTZ (p 1032) describes the post mortem findings in *P. falciparum* malaria. She makes the point that in the brain lesions the vessels are rather distended than obstructed by parasitized erythrocytes though thrombi are occasionally found in vessels associated with haemorrhage. She describes and discusses the findings in the kidneys, but for this the original should be consulted. In discussing the heart lesions observed in fatal *P. falciparum* malaria, MERKEL

(p. 172) comments on the fact that parasitized red cells adhere to capillary walls and that endothelial cells are swollen. The result must be anaemia, and, in fact, the lesions resemble infarcts, for the coronary collateral circulation is poor. Anaemia of the heart may be as important as occlusion of cerebral vessels.

A description of the cytology of bone marrow in malaria is given by LANZA (p. 168). A study of the blood and bone marrow as affected by malaria, is reported by MUKHATCHEVA (p. 494) but details should be sought in the original abstract.

BELTRÁN and DÁVALOS (p. 980) show that examination of fresh blood is efficient for demonstration of malaria parasites as an emergency measure, if staining is impossible.

In discussing splenic indices, GÓMEZ MARCANO (p. 390) makes certain suggestions on matters of detail, which are important. These should be sought in the original abstract.

DELL and KLINEFELTER (p. 171) discuss their radiological studies on spleen size, but their findings should be sought in the original.

TORON (p. 278) and PULLEN (p. 790) report cases of spontaneous rupture of enlarged spleen in malaria.

ZERMATI and VARGUES (p. 869) have found, as others have found, that the complement titre falls during the course of malaria (as in other infections) and rises after cure. In severe cases, persistent absence of complement indicates the probability of a fatal ending—progressive rise in titre preceded cure. This is a non-specific phenomenon, more marked in *P. falciparum* than in *P. vivax* infections.

MAYER and HEIDELBERGER (p. 172) have studied the complement-fixation reaction in malaria, using for the purpose antigens from various plasmodia. For latent malaria the test has only limited value but if syphilis is excluded, a positive reaction is specific for malaria. It seems that the malaria antigens contain a Wassermann antigen which is distinct from them. GORDON *et al.* (p. 173) report that a complement-fixation test with an antigen from *P. gallinaceum* is not of much value in detecting latent malaria.

MELNICKY (p. 492) sums up part of the literature dealing with the changes in physiological processes resulting from malaria. He deals, for instance, with blood proteins, blood sugar, blood electrolytes, and anaemia. For details the original should be consulted. GALL and STEINBERG (p. 878) show that in malaria and in artificial fever there is a fall in serum inorganic phosphorus, and a rise in blood glucose—they discuss the implications of these and related findings.

BIANCO *et al.* (p. 1034) as a result of observations made on 1,500 attacks of malaria in U.S. naval men, make the point that a large proportion of them gave positive reactions with most of the ordinary tests for syphilis, but the tests usually became negative within 4 weeks.

TRIMARCHI (p. 168) reports that Ascoli's adrenaline treatment restores the fixing capacity of the reticulo-endothelial system to normal in malaria, as shown by the results of the Congo red test.

CARLSON *et al.* (p. 174) describe a colorimetric test which may be significant in diagnosis, though it is probably not specific.

MAHARI (p. 279) finds fairly good correlation between the cephalin-cholesterol flocculation test and spleen and liver enlargement in malaria, and that the shorter the infection, the stronger the reaction.

MACHELLA *et al.* (p. 557) report a relationship between retention of injected bromsulphthalein and the intensity of malarial fever.

LIPPINCOTT *et al.* (p. 166) have investigated liver function in patients with induced *P. vivax* malaria, and conclude that although there is some dysfunction

during the attack, this passes off when effective treatment is given. Somewhat similar findings are also reported by GLENN *et al* (p 167). Having performed liver function tests on a series of patients with *P. vivax* malaria, SCHNEIDER and SHALLENBERGER (p 1033) conclude that although there is some evidence of transitory liver damage in a proportion of patients, permanent damage is rare. BUTLER and SAPERO (p 1034) show that American Negroes were as susceptible as white troops to malaria on an island in the South Pacific. LAMBILLON (p 1034) describes patients with lesions resembling erysipelas, apparently resulting from malaria. SPRAGUE (p 25) thinks that the possibility of cardiac damage from recurrent malaria is extremely remote.

KARK (p 170) gives reasons for thinking that the risk of activating latent malaria by surgical operations has been somewhat over-emphasized. DI COSTA (p 558) enters the warning that patients with fever of malarial type, who do not respond to anti-malaria treatment, should be examined for tuberculosis.

SHUTE (p 169) defines latent *P. vivax* malaria as an attack in a patient who has been infected several months before the onset of symptoms. The delay may be due to drug suppression, immunity, or infection with two species, or it may be related to the number of sporozoites inoculated, since it occurs only with small numbers. Relapses, on the other hand, are due to activity of the parasites after a resting phase.

From an analysis of the records of malaria in Samarkand, GEVORKOV (p 486) concludes that during the first half of the year 5-12 per cent of the cases are primary infections with long incubation periods.

BELTRAN and SAYDOVIL (p 961) have found that when malaria is induced by injection of infected compatible blood, the incubation period lasts only 1-3 days, but that with incompatible blood it is never less than 5. KAPLAN *et al* (p 281) give advice (which should be sought in the original) as to the best dosage of blood containing *P. vivax* for the induction of therapeutic malaria. KAPLAN *et al* (p 25) have shown that men infected with *P. vivax* in the Pacific show considerable immunity if re-inoculated with similar strains, satisfactory courses of neurosyphilis but that with heterologous strains, satisfactory courses of neurosyphilis can be given. ENGSTROM *et al* (p 961) report on patients treated in America, for neurosyphilis, by induced malaria with strains from the Pacific and the Mediterranean.

CITCA *et al* (p 561) have hyper-immunized patients submitted to malaria therapy by repeated inoculation of various strains of parasites of the three common species. Tests carried out during 14 years after this procedure indicate that immunity to *P. malariae* lasts longest and may persist after parasites have been eliminated. With *P. vivax* immunity is usually but not always associated with persistence of the parasites. *P. falciparum* gives the least immunity, probably because its antigens act for a short time only, nevertheless a degree of immunity may be detected several years after cessation of activity.

CHRISTIANSON *et al* (p 24) show that in a minority of relapses occurring in the United States of *P. vivax* malaria contracted in the Pacific or the Mediterranean the patient may show parasitaemia without fever for a few days. A few of such patients may have gametocytes in the blood but there is no serious risk of infecting local mosquitoes on a big scale. KITCHEN and PUTNAM (p 23) give detailed observations on the character of the provisos of mosquito induced malaria with the McCoy strain of *P. vivax*. These cannot satisfactorily be abstracted further.

In discussing the characteristics of *P. vivax* malaria in children in the Panama Canal Zone, FISHER (p 695) remarks that cerebral and algid forms.

(p. 172) comments on the fact that parasitized red cells adhere to capillary walls, and that endothelial cells are swollen. The result must be anaemia, and, in fact, the lesions resemble infarcts, for the coronary collateral circulation is poor. Anaemia of the heart may be as important as occlusion of cerebral vessels.

A description of the cytology of bone marrow in malaria is given by LAYZA (p. 168). A study of the blood and bone marrow as affected by malaria, is reported by MUKHATCHEVA (p. 494) but details should be sought in the original abstract.

BELTRÁN and DÁVALOS (p. 960) show that examination of fresh blood is efficient for demonstration of malaria parasites as an emergency measure, if staining is impossible.

In discussing splenic indices, GÓMEZ MARCAYO (p. 390) makes certain suggestions on matters of detail, which are important. These should be sought in the original abstract.

DELL and KLINEFELTER (p. 171) discuss their radiological studies on spleen size but their findings should be sought in the original.

TORODE (p. 278) and PULLEN (p. 780) report cases of spontaneous rupture of enlarged spleen in malaria.

ZERMATI and VARGUES (p. 956) have found, as others have found, that the complement titre falls during the course of malaria (as in other infections) and rises after cure. In severe cases, persistent absence of complement indicates the probability of a fatal ending—progressive rise in titre preceded cure. This is a non-specific phenomenon, more marked in *P. falciparum* than in *P. vivax* infections.

MAYER and HEIDELBERGER (p. 172) have studied the complement-fixation reaction in malaria, using for the purpose antigens from various plasmodia. For latent malaria the test has only limited value, but if syphilis is excluded, a positive reaction is specific for malaria. It seems that the malaria antigens contain a Wassermann antigen which is distinct from them. GORDON *et al.* (p. 173) report that a complement-fixation test with an antigen from *P. gallinaceum* is not of much value in detecting latent malaria.

MELNICKY (p. 492) sums up part of the literature dealing with the changes in physiological processes resulting from malaria. He deals, for instance, with blood proteins, blood sugar, blood electrolytes, and anaemia. For details the original should be consulted. GALL and STRINBERG (p. 876) show that in malaria and in artificial fever there is a fall in serum inorganic phosphorus, and a rise in blood glucose—they discuss the implications of these and related findings.

BIANCO *et al.* (p. 1034) as a result of observations made on 1,500 attacks of malaria in U.S. naval men make the point that a large proportion of them gave positive reactions with most of the ordinary tests for syphilis, but the tests usually became negative within 4 weeks.

TRIMARCHI (p. 166) reports that Ascoli's adrenaline treatment restores the fixing capacity of the reticulo-endothelial system to normal in malaria, as shown by the results of the Coogo red test.

CARLSON *et al.* (p. 174) describe a colorimetric test which may be significant in diagnosis, though it is probably not specific.

MAKARI (p. 279) finds fairly good correlation between the cephalin-cholesterol flocculation test and spleen and liver enlargement in malaria, and that the shorter the infection, the stronger the reaction.

MACHELLA *et al.* (p. 557) report a relationship between retention of injected bromsulphthalein and the intensity of malarial fever.

LEFFINCOTT *et al.* (p. 168) have investigated liver function in patients with induced *P. vivax* malaria, and conclude that although there is some dysfunction

CANAPERIA, G A *Malaria in Italy during the War and Post-War Period.*
Bull Office Internat d'Hyg Publique 1946, Oct-Nov-Dec, v 38,
 Nos 10-11-12 1070-76 [French version 1062-9]

As a result of antimalaria measures, the progressive reduction of malaria morbidity and mortality in Italy culminated in 1940 when the figures were the lowest ever recorded 55,453 cases and 488 deaths as compared with 249,529 cases and 11,477 deaths in 1918. The recent war had a disastrous effect on the malaria situation. The destruction of bridges preventing the free flow of water and resulting in marsh formation, the destruction of dykes and drainage works producing vast inundations, increasing difficulty in maintaining antilarval work, the dispersal of trained staff engaged on antimalaria work, the progressive scarcity of antimalaria drugs, overpopulation of endemic areas in which living conditions were precarious, the presence of non-immune troops in endemic areas who became infected, and the systematic removal of cattle by the enemy, were all factors responsible for greatly increased malaria incidence. This increase occurred wherever the two chief vectors of Italian malaria were present—*A. maculipennis labranchiae* in central and southern Italy, Sicily and Sardinia, and *A. sacharovi* along the coast-line of Venetia and Emilia. In areas where the much less important vectors *A. maculipennis* marked exacerbation of the disease. In 1942 the registered number of cases and deaths had risen to 164,082 and 1,075, in 1944 to 373,941 and 422 and in 1945 to 411,602 and 386.

Since the cessation of hostilities energetic antimalaria measures have been restarted with the cooperation of UNRRA and the Rockefeller Foundation. Conditions have improved. In certain areas DDT has been used with great success. A vast plan of control with DDT in all endemic areas was decided upon, in collaboration with UNRRA. The Rockefeller Foundation is directing a scheme for the eradication of anophelines from Sardinia by the use of DDT.

FERRARO, F *Variazioni anofeliche nel bacino del Basso Volturno* [Changing Anopheline Prevalence in the Volturno Delta] *Riv di Malariaologia* 1947, Apr, v 27, No 2, 74-9 [12 refs] English summary (7 lines)

War destruction in the Volturno Delta undid the work of years of effort. Bridges, roads and canals were wrecked with the result that the country reverted to conditions that characterized it before bonification. The author reports on the results of an anopheline survey and on the saline content of water in breeding places. *A. maculipennis labranchiae* remains the most prevalent and important vector in the district, but *A. sacharovi* has appeared in places in which it had not previously been reported.

BULL INST HYG MAROC 1945, v 5, 85-95 1 chart *Rapport annuel du Service Antipaludique en 1945* [Annual Report of Antimalaria Service, Morocco, in 1945]

Morocco suffered less than usual from malaria in 1945. During the summer months malaria was less in evidence than were relapsing fever and numerous intestinal infections aggravated by scarcity. In the few localities however where conditions favoured anopheline propagation severe outbreaks of malaria were made more deadly by destitution. The year was abnormally dry after January. The annual number of cases of malaria treated by dispensaries etc from 1940 to 1943 approximated 300,000. In 1945 it was 160,000. This figure is an overstatement, because at the

and that children respond well to treatment with mepracine. EDWARDS and TOMLINSON (p. 363) show that in children admitted to hospital in the Panama Canal Zone for malaria, more than half had *P. falciparum* infections—most of the cases were from rural or semi-rural areas.

PICKERS (p. 277) has found that congenital *P. falciparum* infections are by no means rare in the French Cameroons, yet clinical manifestations are not observed in infants up to the age of 2 months. Malaria is responsible for much of the high infant mortality.

KHAN and TAYLOR (p. 166) report cases of the algid form of *P. falciparum* malaria, in which the signs of shock (with haemo-concentration) responded to fluid replacement therapy with plasma, blood or intravenous fluids.

HILLS (p. 169) reports 24 cases of malarial jaundice, in 5 of which the infection was with *P. vivax* and in 19 with *P. falciparum*. This appears to be haemolytic jaundice and rapid haemolysis may cause haemoglobin to appear in the urine. BERNBAUM *et al.* (p. 22) show that red cells from patients with malaria are laked in bile solution more easily than normal cells, and that although quinine, atabrin and plasmoquine all accelerate this haemolysis, quinine administered *per os* to normal subjects does not do so.

BRONKH *et al.* (p. 280) state that as American Negroes are often refractory to *P. vivax* *P. malariae* should be used for therapeutic purposes. A daily parasite count is desirable in therapeutic malaria—they note that with *P. falciparum* counts of 100 000 to 200 000 per cmm. are on the danger line. This last infection was rarely used.

FISCHER and YORK (p. 25) report transfusion malaria from blood donors who gave histories of quartan malaria 36–42 years before. Charles Walcotts

J. NATIONAL MALARIA SOC. 1947 Sept. v 6, No. 3 208–16. [19 refs.]
 Medical Research in Malarology in the First Postwar Year 1945–46.
 Report of the Committee on Medical Research [HAAS V. H. Chairman]

More than 100 institutions or individuals in the United States and abroad were asked for information regarding medical research in malarology that was being actively prosecuted in 1945–46. The information received is summarized in this report. Thirty-one laboratories in the United States reported on their investigations—these cover all aspects of the subject. The development and testing of new anti-malarial drugs is receiving most attention. Avian strains of malaria are very widely employed. In the United States, 15 laboratories were using avian parasites, 8 were using human and 7 simian parasites. *Plasmodium gallinaceum* was most frequently used. About half the laboratories in the United States were maintaining insectaries.

The response to requests for information lead the Committee on Medical Research to conclude that exchange of information regarding programmes and progress of research would be welcomed by all malarologists.

No significant diminution of the intensified medical research in malarology that characterized the war years had become apparent. It is pointed out, however, that the great majority of U.S. laboratories engaged in this work are dependent to a considerable extent on Federal government financial support.

SCHWITZ, J. with the collaboration of H. BAUMANN Mme. BRUNEL & M. FOET
Recherches sur le paludisme dans la bordure orientale du Congo Belge.
[Investigation of Malaria along the Eastern Frontier of the Belgian Congo.]
Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales.
Mémoires. (Collection in-8°) 1944 v 14 No. 3 216 pp. 9 maps (1
folding) & 42 figs. on 8 pls. [18 refs.]

This volume sets out in much detail the results of a tour of investigation into malaria conditions along the eastern frontier of the Belgian Congo, undertaken on behalf of the Belgian Royal Colonial Institute. The tour embraced the shores of Lake Kivu and the high plateaux surrounding the lake Rutshuru and its neighbourhood, between Lake Kivu and Lake Edward the Semliki Valley between Lake Edward and Lake Albert and the high plateaux overlooking it from the west Kasenyi and neighbourhood, on the south-eastern shore of Lake Albert Irumu and the gold mines at Kilo. The main objects of the tour were the verification of the belief that the high plateaux are free from endemic malaria the determination of the altitude at which such freedom becomes operative, and the study of malaria in mines and plantations among labourers who had been recruited from high altitudes. Recent reports had ascribed outbreaks of sickness, with considerable mortality to malaria, on grounds which the author considered to be altogether insufficient.

In nearly all the numerous localities visited, a study was made of anophelines, adults and larvae. Blood preparations, both thick drop and smear were made from 6,841 individuals. The formidable task of examining these films was carried out in Brussels after the return of the mission.

No evidence of indigenous endemic malaria was found in Rugari (1 700 metres above sea level) Butembo (1 750) Kadjedje (2,150) Kabare (1,950) Numbi (2,200) and Ngweshu (1 790). Endemic malaria was, however found in Nyangazi (1,650 metres) which is very close to Ngweshu south-east of Lake Kivu. The line of demarcation is between 1 700 and 1,800 metres above this, there is no endemic malaria. At the higher altitudes such redoubtable African malaria vectors as *A. gambiae*, *A. foveatus* and *A. marshalls* were never found, though other anophelines, notably *A. christyi* and very occasionally *A. knigi* and *A. transvaalensis* were sometimes plentiful. *A. christyi* is evidently of no importance as a malaria vector.

Special attention was given to two mining areas, Kaduha-Mufwa and Mongwalu and an agricultural district Rutshuru, where severe outbreaks of malaria had been reported. In none of these areas was there evidence of acute malaria, other than a few mild cases, but in one camp Bwat Moko, blood examinations revealed a state of subacute malaria. There were no febrile reactions but there was a very heavy infection of adults with *P. malariae* and a notable proportion of *P. vivax*, parasites which in Africans, in endemic areas, are restricted to the early years of life, before the acquisition of premonition. Such findings indicate malaria of recent origin.

The author briefly indicates some of the many unsolved problems of malaria in Africa that await elucidation, and recalls the recommendation made by him in 1936 to the Malaria Commission of the League of Nations for a coordinated programme of research to be carried out in the different African colonial territories. [See also this Bulletin, 1947 v 44 786.]

SCHWETZ, J, BAUMANN, H & FORT, M Nouvelles recherches sur les anophèles et le paludisme endémique dans l'agglomération de Coquilhatville (Congo belge) [New Investigation of Anopheles and Malaria in Coquilhatville, Belgian Congo] *Ann Soc Belge de Méd Trop* 1947, Mar 31, v 27, No 1, 139-59, 1 map

The unusually low endemicity of malaria in the neighbourhood of Coquilhatville, where *A gambiae* was not found and where *A marshalli* var *moucheti* was the most common anopheline, has previously been described by the authors [this *Bulletin*, 1939, v 36, 777, 1943 v 40, 103] They now present the results of another brief survey carried out in November, 1945

A gambiae was still absent from Coquilhatville though it appeared, in small numbers, in neighbouring villages, *A marshalli* var *moucheti* was still the predominant anopheline The authors subscribe to the opinions expressed by WOLFS that the stratum of limonite (bog-ore) that lies on or near the surface acts as a deterrent to the breeding of *A gambiae* [this *Bulletin* 1947, v 44, 164. Blood examinations once more showed a very low prevalence of malaria parasites were very few in positive smears *P vivax* was not found and *P malariae* was rare Gametocyte carriers were very infrequent *A marshalli* var *moucheti* is evidently a much less effective vector of malaria than *A gambiae* Norman White

REBELO, A O sezonismo em Quelimane [Malaria in Kilimane] *An Inst Med Trop* Lisbon 1946, Dec, v 3, 143-58, 1 fig English summary

Kilimane is a small town in Portuguese East Africa, in the coastal plain that lies to the north of the mouth of the Zambesi River Next to scabies and yaws, malaria is the most prevalent disease Among a population of 2 077, the annual number of malaria cases registered, between 1941 and 1944, varied from 881 to 2,129 The spleen rates of children in different parts of the town ranged between 58 and 77 per cent, and the parasite rates between 47 and 66 per cent The percentages of plasmodia found in films were *P falciparum* 97.9, *P malariae* 2.7 and *P vivax* 2.2 Of 573 anophelines captured in dwellings, *A funestus* formed 71 per cent, the remainder were *A gambiae* The sporozoite rates were *A funestus* 3.1 (157 dissections) *A gambiae* 5 per cent (60 dissections) Norman White

FAUST E C, SCOTT, J A & McDANIEL, G E Malaria Mortality and Morbidity in the United States for the Year 1945 *J National Malaria Soc* 1947 Sept, v 6, No 3, 184-91, 2 figs

Previous reports in this series showed the considerable increase in malaria mortality in the United States that synchronized with the economic depression of the mid-1930's and the subsequent substantial yearly decrease in mortality in practically every malarious State During the recent war years, conditions were complicated by the establishment of large military centres in highly malarious areas and the return of innumerable military personnel and prisoners of war from hyperendemic malarious areas overseas In spite of these conditions the 1945 civilian malaria mortality figures are highly satisfactory The total civilian deaths for 1945 numbered only 399, as compared with 584 in 1944 and 622 in 1943 In 1935, there were 4,268 certified deaths from malaria meanwhile the population has increased perhaps 10 per cent There are still hyperendemic malaria areas in the south-eastern States, in the Mississippi valley, in eastern Oklahoma and Texas and in the lower Rio Grande Case-reporting of malaria is insufficient to provide accurate information of

the distribution and intensity of the disease, except in the States of South Carolina, Mississippi and Texas.

As in previous years, the basic data were obtained from the bureaux of vital statistics of each of the States.

PIÑERO GARCÍA, P. P. Endemiografía del paludismo en la provincia de Santa Fe. [Distribution of Malaria in the Province of Santa Fe.] *Kuba*. Habana. 1947 Apr., v 3 No. 4, 95-8.

This paper contains a general description of the distribution of malaria in Argentina and a more detailed description of the topography and malaria incidence in the Province of Santa Fe. This province occupies the territory between the Parana River and the eastern frontier of Argentina. It contains 19 departments grouped into northern central and southern zones. During nine years 2,497 cases were registered in the Province, 2,002 of these being in the northern zone. One of the northern departments, General Obligado was alone responsible for 1 622 cases, 916 of them in a single year 1941. *P. vivax* is the prevailing type of infection. It is probable that most if not all of the cases reported from the central and southern zones were relapses of infections acquired in the northern zone or elsewhere.

DRANE, L. M. Observações sobre a malária na Amazônia brasileira. [Observations on Malaria in the Amazon Region, Brazil.] *Rev. Serviço Especial de Saúde Pública*. Rio de Janeiro. 1947 v 1 No. 1 3-60 3 maps & 3 graphs. (30 refs.) English summary

This report gives a summary of observations made by the Special Public Health Service between July 1942 and June 1946 on the distribution and transmission of malaria in the Amazon Region of Brazil. This huge territory of some 3 600,000 square kilometres comprises 41.5 per cent. of the total area of Brazil but has an estimated population of only one and a half million. The observations included the examination of 185,214 blood films and 43 496 spleens in 76 localities the results of which are tabulated. The over-all parasite rate was 3.1 per cent. the spleen rate 12.8 per cent. There were striking differences in the degree of malaria endemicity in different parts of the territory. The incidence of species of *Plasmodium* in the positive blood slides was *P. vivax* 63.2 *P. falciparum* 36.8 and *P. malariae* 0.2 per cent.

The examination of 562,054 adult anophelines and 1,360 734 larvae from 115 localities revealed the presence of 30 species and varieties, which are listed. The only important vectors of malaria are believed to be *A. darlingi* and *A. aquasalis*. The former was found throughout the region. *A. aquasalis* was confined to coastal districts. *A. albopictus* var. *domesticus* was very abundant in some areas but did not appear to be as important a vector in the Amazon as it is reputed to be in other parts of Brazil.

House-spraying with DDT-kerosene solution promises to be a valuable control measure for *A. darlingi*. [See also this Bulletin 1948 v 43 287.]

Norman White

PIROTTI, M. A malária no Brasil. [Malaria in Brazil.] *Folha Med.* 1947 June 25 & July 5 v 28 Nos. 12 & 13 156 pp. 13 figs. & 2 maps.

A description is given of the constitution, organization and functions of the National Malaria Service of the National Health Department of the Ministry of Education and Health of Brazil, which was inaugurated in 1941. It consists of an Epidemiological Section, a Section of Organization and Control, a

Section of minor hydraulic engineering work, an Administration Section, and an Institute of Malariology

A list is given of all localities in all the *municípios* of Brazil from which endemic malaria has been reported, this list occupies 132 pages

Fifty-four species of anophelines have been identified in Brazil. The distribution of these according to States is presented in graphic tabular form. Apart from *A. gambiae* which, imported from West Africa, played an important localized rôle in the transmission of malaria until it was eliminated, eight species have been found naturally infected with malaria, *A. darlingi*, *A. albicans*, *A. tarsimaculatus*, *A. stroderi*, *A. noroestensis*, *A. (Kerteszia) cruzi*, *A. (K.) bellator* and *A. (K.) homunculus* (?)

A. stroderi, though widely distributed, is probably of little or no practical importance as a vector. This also applies to *A. noroestensis*. The three species of *Kerteszia* are limited to the States of São Paulo, Paraná, Santa Catarina and Rio Grande do Sul, where bromeliads provide facilities for their breeding. *A. darlingi* is the most redoubtable vector of all.

The report gives some illustrations of excellent drainage work of several species of bromeliads and of the work being done to control *Kerteszia*

WHITE, R Senior, RAMAKRISHNA, V & RAO, V V **Malaria on the North Madras Coast** *Indian J Malariology* 1947, Mar, v 1, No 1, 81-109, 1 graph [11 refs]

The area dealt with in this report is a narrow coastal plain between the Eastern Ghats and the Bay of Bengal, from the Rushikuliya River southward to the Vamsadaha River. It is mostly not more than ten miles in width. Only two rivers traverse the plain both rise from the eastern face of the Ghats and are seasonal in their flow. Until ten years ago, this area of India was reputed to be completely free from malaria. In 1938 *A. sundarcus* was discovered in the coastal village of Naupada, associated with malaria prevalence. Each year thereafter until 1945, extensions of *A. sundarcus* were reported. These findings are summarized and tabulated.

In some places in the area, *A. stephensi* is the malaria vector, in others both *A. stephensi* and *A. sundarcus* are responsible.

Reports on the salinity of *A. sundarcus* breeding places are summarized. It would seem that salinity of 100 parts per 100,000 is the optimum for oviposition, but no less than 50 per cent of the total larval production occurs in waters with a salinity between 700 and 1,000 parts per 100,000. These findings suggest the existence of two races of *A. sundarcus*. The freshwater race is possibly a more efficient vector than the other. Further evidence is adduced favouring the hypothesis that two races exist.

Norman White

RAO T R **Visual Responses of Mosquitoes artificially rendered Flightless.** *J Exper Biol* 1947, Sept, v 24 Nos 1/2, 64-78, 6 figs

Normal mosquitoes are known to avoid the light in the daytime but most of them tend to fly out of their dark shelters at dusk.

This paper describes experiments with mosquitoes (*Culex molestus* and *Anopheles maculipennis atroparvus*) prevented from flying by amputation of the wings or by fixing the wings together. It was thought that this method would allow more accurate measurement of their responses.

It was found that the mosquitoes, placed in a small arena illuminated from below, would always walk towards a dark section of the wall. This

occurred wherever the black band was placed in their field of vision, provided that it was sufficiently wide to subtend an angle of 8° on the mosquito's eye.

Contrary to expectations, there was no change in the insect's avoidance of light at dusk. About 10 per cent. of the mosquitoes were slightly abnormal in their directional response towards the black band but only one out of all the specimens investigated actually moved towards the light.

J R BARNES

VOGT G B Salinity Tolerance of *Anopheles quadrimaculatus* and Habitat Preference of *A. crucians bradleyi* J Econom. Entom. 1947 June, v 40 No 3 320-25.

The purpose of this paper is to establish for one locality a carefully defined example of appreciable salinity tolerance of *Anopheles quadrimaculatus* which is generally regarded as a distinctly freshwater anopheline. Notes on *A. crucians bradleyi* and *Culex salinarius* are also included.

The investigation was made in the vicinity of Scotland, St. Mary's County Maryland, U.S.A. Sampling stations in Deep Creek were selected because they gave a range of salinities from minimum to maximum values. The sampling methods and characteristics of the creek are described.

Larvae were found in the north arm of the creek where salinity ranged from 1,400 to 2,800 ppm. soluble chlorides but they did not occur in the south arm where the salinity was from 4,400 to 6,300 ppm. although the pH and the plant coverage were similar in both places. On one occasion in the south arm, larvae were found after an original salinity of 2,900 ppm. soluble chlorides had increased to 5,200 ppm. but these were survivors whose development had begun at the lower salinities. From the results of the observations which are summarized in four tables, it is concluded that the salinity tolerance of *A. quadrimaculatus* may be as high as 2,900 ppm. soluble chlorides.

The only other mosquitoes associated with *A. quadrimaculatus* were *A. crucians bradleyi* and *Culex salinarius*. The distribution of the larvae of these two species seemed to be unrelated to salinity. They were found in the marshy ground between the two arms of the creek only in the spring and autumn were they collected from the exposed water surface associated with the Sago pond-weed.

RACHOU R G & FERREIRA M O As *Aedes* como os grandes responsáveis pela malária no litoral do Estado de Santa Catarina. [The *Aedes* Mosquitoes as Prevalent Vectors of Malaria in Litoral of the State of Santa Catarina, Brazil.] *Folia Med.* 1947 Jan. 5 v 28, No. 1, 8 pp.

MACGRAITH, B., ANDREWS W H. H. & GALL, D A Hepatic Syndrome of Wide Distribution Illustrated by Lesions in Malaria and Blackwater Fever *Lancet.* 1947 Nov 29 781-4 [73 refs.]

In fatal cases of malaria, necrosis of the liver cells occurs in the inner two-thirds of the lobule, being most prominent in the cells surrounding the central veins and sinusoids, which may be deeply congested. This hepatic lesion resembles that resulting from right-sided heart failure associated with tissue anoxia arising from interference with escape of venous blood from the liver. As right-sided heart failure is not a feature of malaria, some other factor must be involved in the obstruction to the outflow from the liver of venous blood. Histological evidence gives no support to obstruction by agglutination of red

cells, thrombosis or degenerated Kupffer and littoral cells. The authors suggest that in malaria, blackwater fever and various other conditions in which the same lesions arise from stagnant anoxia, the obstruction to the venous flow from the liver is brought about by reflex constriction of some part of the hepatic venous tree. It is difficult to understand why the anoxia should affect the cells at the centre of the lobule only, but it is supposed that some process exists which permits the peripheral cells to remove the oxygen from the blood. The constriction is brought about by nervous reflexes which may have their origin within or outside the liver. If arising outside the liver, they probably account for the relationship between hepatic and renal disturbances.

DUBOIS, A. Observations sur la pathologie paludéenne chez les indigènes de Pawa (Nepoko) [Observations on the Pathology of Malaria among the Natives of Pawa (Nepoko)] *Ann Soc Belge de Méd Trop* 1947, Mar 31, v 27, No 1, 17-24

The author has noted a much higher incidence of splenomegaly among adult females than among adult males in Pawa, Belgian Congo. There is no other evidence that females suffer more from malaria than males. The phenomenon appears to be due to the greater relaxation of visceral ligaments and of the abdominal wall that characterizes the female. In routine examinations the spleen is palpated with the patient standing. The splenic index may thus be misleading unless it be confined to children. The curve of age incidence of malaria in Pawa differs somewhat from that found in most other parts of the Belgian Congo at similar altitudes. Pawa is 800 metres above sea-level. Maximum spleen and parasite rates are attained at slightly older ages, this is attributed to the relatively low anopheline density in Pawa.

WHORTON, C M, PULLMAN, T N, KIRSCHBAUM, W R, JONES, R Jr, ALVING, A S, CRAIGE, B, Jr, EICHELBERGER, Lillian & COULSTON, F. The Chesson Strain of *Plasmodium vivax* Malaria. IV Immunity. *J Infect Dis* 1947, July-Aug, v 81, No 1, 1-6, 2 figs [25 refs]

In previous communications, the authors have described certain characteristics of induced malaria with the Chesson strain of *P. vivax*, of New Guinea origin [this *Bulletin*, 1948, v 45, 139-40]. In this paper, immunity acquired from such infection is described. In 135 primary attacks of sporozoite-induced infections, the onset of fever occurred when the average parasite count was 10 parasites per cmm. With the first and second relapses, there was a progressive increase in the parasite density at the onset of fever, but with the third relapse the pyrogenic threshold did not differ significantly from that of the second. Similarly, in trophozoite-induced infections the threshold at the onset of clinical reactivation was higher than at the onset of the first period of clinical activity.

In trophozoite-induced infections, peak parasitaemia was noted on the 12th day on the average with a range of 5 to 46 days. Parasite densities were higher than those reported with indigenous strains, the mean maxima in 95 patients being 33,000 parasites per cmm of blood (2,600 to 90,000). Negroes were refractory to infection with trophozoites.

In white subjects, acquired immunity, to both homologous and heterologous strains, was demonstrated.

Norman White

The first patient was happily married, free from worries, and from any history of mental disorder. She received a total of 1.8 gm. of mepacrine over four days for the treatment of a proved *P. falciparum* infection and responded so rapidly that she felt well on the fourth day. She retired to bed at 9.30 and chatted, apparently cheerfully and normally with her husband. The next morning, the husband awoke to find that his wife had disappeared. Her body was found soon after in the river and death was shown to be due to drowning, without evidence of other abnormalities.

The second patient had suffered from claustrophobia after shell-shock during the 1914-18 war but had recovered by 1924. He had also suffered recently from subtertian malaria and had 1.8 gm. of mepacrine in 5 days, followed by 10 grains of quinine dihydrochloride t.i.d. from the sixth to the tenth day. On the sixth evening the patient felt sick after taking quinine, and on the seventh, without medical advice, he reverted to mepacrine (0.1 gm. t.i.d.). On the evening of the ninth day (after he had taken a total of 2.4 gm. of mepacrine) the patient went to his bath at 8 p.m. where he felt a feeling of unreality coming over him. He then found himself sitting, naked and wet, in his dining-room and this amnesia lasted for about half an hour. Immediate stoppage of mepacrine resulted in no further ill-effects [see also FINDLAY this *Bulletin*, 1947 v 44 763].

HOODLER, S. W. Psychotic Reactions to the Ingestion of Large Doses of Quinacrine in Normal Subjects. *Amer. J. Trop. Med.* 1947 July v 27 No. 4 477-81

Thirty-one medical, dental and medical administrative corps officers volunteered to take quinacrine (mepacrine) at first in suppressive and then in therapeutic dosage. None had ever had malaria, nor were they in an endemic area. The dosage was 0.1 gm. daily for 1-2 weeks, 0.1 gm. twice daily for one week, and finally 0.4 gm. three times one day, 0.3 gm. three times the next day and 0.1 gm. three times daily for the next four days. Twenty-four of these officers developed toxic central nervous system symptoms varying from mild insomnia and depression to severe psychotic reactions in three cases. The symptoms subsided promptly on discontinuing the drug. The most toxic reactions occurred in two persons with a previous history of depression. The worst and most prolonged effect occurred in the case of an officer who exceeded the above dosage. He took 0.5 gm. instead of 0.3 gm. on the third (? second day) of intensive dosage. The earliest manifestations of cerebral toxicity are insomnia, restlessness, increased dreaming, and mild depression or elation. [See above.]

Twelve cases of acute malaria, ten *P. vivax* and two *P. falciparum* infections, were treated with paludrine. The dose given to adults was 0.10 gm. thrice daily for five or six days. The symptoms were relieved and asexual parasites disappeared from the peripheral blood in less than 60 hours in all cases.

AFRIDI, M K, RAMAKRISHNAN, S P, GOSWAMI, A & MENON, M K. An Enquiry on certain Aspects of Paludrine. *Indian J Malariology* 1947, Mar, v 1, No 1, 221-9

This describes an inquiry to determine the optimum single dose of paludrine for the control of the clinical symptoms of malaria. For this purpose two villages, Kechi Beg and Ahmad Kanzai, four and six miles south of Quetta, Baluchistan, were selected. Here malaria is highly endemic, but the transmission season is of only about 12 weeks' duration. The spleen rates in these villages were 23.6 (June) and 69.6 (September), and the parasite rates 1.97 and 4.3 per cent respectively. The inquiry lasted from July 6 to October 2. Transmission is low in July and August but at its height in September. Villages were preferred to a hospital, for this inquiry, because the follow-up of patients presented fewer difficulties. A single-room hut in the centre of each village served as a dispensary, patients were received daily six days a week.

Patients suffering from fever, with malaria parasites in their blood, were treated with either (1) One tablet of paludrine, 100 mgm, (2) a single dose of 3 tablets, 300 mgm, (3) two tablets of paludrine twice a day as long as the patient attended (up to 3 days), or (4) three tablets of mepacrine a day in two doses as long as the patient attended (up to 3 days).

Altogether, 563 patients were treated, records regarding the day of disappearance of fever and parasites are available for 241 cases. The single dose treatments with either 100 or 300 mgm paludrine caused abatement of fever and disappearance of parasites within 3 days, in a high proportion of cases. Multiple doses in treatment (3) gave no significantly better results than treatment (2). Mepacrine gave no better results than treatments (2) and (3) although a slightly smaller proportion of patients treated with mepacrine returned with second attacks. The conclusion was that the optimum single dose of paludrine to obtain a nical cure of a malarial attack was 300 mgm.

SS INSTITUTE OF TROPICAL HYGIENE (INDIA BRANCH) Report to the Committee of Control of the Ross Institute (India Branch) on the Control of Malaria in Industrial Labour Forces in India [MACDONALD G, M D, DPH, DTM, Director of the Ross Institute of Tropical Hygiene, Keppel Street, Gower Street, London, WC 1] pp iii+72, 8 figs 1947

One of the objects of an extensive tour made by the author in the north-east and south of India was to enquire and report on the extent to which recent developments in malaria control can be economically adapted to the needs of industry in India. It was clear that recent developments could not be considered without regard to existing practices with which they must be integrated. The result is this very useful pamphlet which deals with the whole subject of malaria control in this part of the world, with special reference to new weapons which wartime research has made available, new antimalarial drugs, DDT, Gammaxane, etc. The pamphlet is not intended for the expert malarialogist. It is concise and clear and should be of great value to medical officer and layman alike who are concerned with these problems and who have an elementary knowledge of malaria.

In the parts of India with which the author is concerned, the most important malaria vectors are *A. annulus*, *A. philippinensis*, *A. culicifacies* and *A. fluviatilis*, but many of the author's recommendations are of general application, whatever the vector may be. It appears that DDT in India has been discredited, chiefly on account of the grossly inadequate quantities that had been applied. This arose from the

The first patient was happily married, free from worries, and from any history of mental disorder. She received a total of 1.8 gm. of mepacrine over four days for the treatment of a proved *P. falciparum* infection and responded so rapidly that she felt well on the fourth day. She retired to bed at 9.30 and chatted, apparently cheerfully and normally with her husband. The next morning the husband awoke to find that his wife had disappeared. Her body was found soon after in the river and death was shown to be due to drowning, without evidence of other abnormalities.

The second patient had suffered from claustrophobia after shell-shock during the 1914-18 war but had recovered by 1924. He had also suffered recently from subtertian malaria and had 1.6 gm. of mepacrine in 5 days, followed by 10 grains of quinine bishydrochloride t.d.s. from the sixth to the tenth day. On the sixth evening the patient felt sick after taking quinine, and on the seventh, without medical advice, he reverted to mepacrine (0.1 gm. t.d.s.). On the evening of the ninth day (after he had taken a total of 2.4 gm. of mepacrine) the patient went to his bath at 8 p.m. where he felt a feeling of unreality coming over him. He then found himself sitting, naked and wet, in his dining-room and this amnesia lasted for about half an hour. Immediate stoppage of mepacrine resulted in no further ill-effects [see also FINDLAY this Bulletin 1947 v 44 763] H J O'D Burke-Gaffney

WOODRUFF A. W. The Suppressive and Schizonticidal Values of Paludrine (100 mg.) in Vivax Malaria. *Trans Roy Soc. Trop. Med. & Hyg.* 1947 Oct. v 41 No. 2, 283-7 1 chart.

Twenty patients suffering from *P. vivax* malaria were treated with paludrine. Most of the patients were ex-prisoners of war from the Far East. All had had previous attacks of malaria, varying in number from one to twenty; most had had relapses since repatriation. Each patient admitted to hospital for a malaria attack was treated with a single tablet of 100 mgm. of paludrine only. On discharge from hospital, each patient was given 25 of these tablets with instruction to take one each week. A year after admission to hospital, that is, six months after the completion of the paludrine course, a questionnaire was sent to each patient asking for information about long-term and short-term relapses.

During the acute attack, the response to a single dose of paludrine was slow but the attack was controlled in all cases. The temperature fell to normal in 12 hours in only 7 of 15 cases; in 3 cases the febrile period lasted more than 48 hours after the administration of the drug. The dose of 100 mgm. is probably sub-optimal and should be increased.

During the period of 6 months in which the patients were receiving 100 mgm. paludrine weekly, one relapse was seen and three other possible clinical attacks were reported.

During the 6 months immediately after the 6 months of suppressive paludrine, there was one long-term relapse and one other possible clinical relapse.

No toxic manifestations were seen at any time.

KENNEY M. & BRACKETT S. The Effectiveness of Metachloridine in suppressing Natural Infections with *Plasmodium malariae* and *P. falciparum* in British Guiana. *Amer J Trop Med.* 1947 July v 27 No. 4 483-501 [11 refs.]

Metachloridine (2-metanillamido-5-chloropyrimidine) was tried as a suppressive of malaria in British Guiana. For this purpose four schools in the neighbourhood of New Amsterdam were selected. The children in these schools are children of labourers on sugar estates. Negroes and East Indians are about equally represented. The schools are in a flat coastal area where suitable breeding places for *A. darlingi*, the chief vector, abound.

The treated group and the control group each consisted of 250 children. Treatment lasted from February 4 to April 17 and from May 6 to July 28, 1948; the interval was the Easter holiday. Up to May 30 each treated child received the appropriate proportion of the adult dose, one gramme per week, divided into 2, 3 or 5 parts; the weight of the child determined the dose. On May 30 the dosage was doubled. Blood smears were examined just before treatment was started, immediately after the Easter holiday, 50 days after the termination of treatment and at intervals of 3 weeks during treatment.

Before treatment, 9 of the control group and 8 of the treated group harboured *P. malariae*. During treatment, there were 58 positive *P. malariae* slides (35 children) in the control group; none in the treated group. Metachloridine is a highly effective suppressant of *P. malariae*.

During treatment, there were 93 positive *P. falciparum* slides (60 children) in the control group, 37 (24 children) in the treated group. The reduction in *P. falciparum* parasitaemia as compared with the control group was 40 per cent during the period of one gramine dosage, and 72 per cent with two grammes. No symptom of toxicity was ever seen.

There were 11 positive *P. vivax* slides in the control group, only one in the treated group, possibly owing to failure to take the drug. *Norman White*

FRAVIS, B. V. Relative Effectiveness of various Repellents against *Anopheles farauti* Laveran. *J. National Malaria Soc.* 1947, Sept., v. 6, No. 3, 180-83.

Tests were done at Guadalcanal with a small cage, and at Efate with a large insectary. Volunteers exposed their treated and untreated limbs simultaneously to this mosquito, and noted the times for the first bite on the treated areas.

An earlier paper (Fravis *et al.*, *J. Econom. Entom.*, 1946, v. 39, 627) showed that while one compound was the most effective repellent for a certain biting insect, another might be better against a different insect. The present paper provides more data to support this conception because the standard repellents dimethyl phthalate and Indalone were found to be of only moderate value against *A. farauti*. The compound R 612 (2 ethyl-1,3-hexanediol) and certain other substances (such as undecylenic acid) were much better.

It was concluded that a mixture of repellents was more satisfactory than any single one. The 6:2:2 mixture (dimethyl phthalate R 612 and Indalone) was fully satisfactory against *A. farauti*. *J. R. Busvine*

TOSKING, H. D., LAVOIEPPE, R. & COURTOIS, C. M. A Small Scale Experiment in the Use of DDT in Mauritius. 5 pp. 1946. Port Louis. J. H. Bowkett, Govt. Printer. (10 cents.)

In a small scale experiment during the period December, 1945 to March, 1946, the authors demonstrated to their own satisfaction that DDT applied as a residual insecticide (5 per cent DDT in kerosene) to the type of labourer's dwelling found in Mauritius resulted in a pronounced reduction in the numbers of *A. farauti* and *A. gambiae* caught by hand in those dwellings. The procedure was welcomed by the populace concerned and it was decided to experiment further on a larger scale to determine the effect of this residual insecticide on the incidence of malaria. [See below.] *R. Ford Fradre*

NASH, T A M A Record of *Syntomosphyrum glossinae* from Nigeria *Bull Entom Res* 1947, Dec, v 38, Pt 3, 525

Some 23 years ago LLOYD *et al* [this *Bulletin*, 1927, v 24, 891] attempted unsuccessfully to introduce the Chalcidid pupal parasite *Syntomosphyrum glossinae* into a part of Northern Nigeria as a measure of control of tsetse flies [A similar experiment had been tried with little success by LAMBORN in Nyasaland (*ibid*, 1925, v 22, 291)] It is suggested that the seasonal high temperature and low humidity were responsible for the failure of the experiment

The present author now records that in April 1947, the laboratory stock of *Glossina palpalis* puparia from the Kaduna area (which is 210 miles south-west of Sherifuri, where LLOYD *et al* had experimented, in breeding sites of *G morsitans* and *G tachinoides*), suddenly became heavily infested with *S glossinae* It is presumed that an infected pupa had been brought in from the bush and had initiated the mass infestation of the offspring

The author concludes that *S glossinae* is indigenous in Nigeria and that its presence cannot be attributed to the abortive efforts of LLOYD *et al* twenty-three years ago

[The reference to LLOYD and JOHNSON given by the author appears to be incorrectly quoted it presumably refers to LLOYD, JOHNSON and RAWSON (*Bull Entom Res*, 1927, v 17, 423, referred to above) and not to "Lloyd and Johnson (*Bull Entom Res* 27, p 449, 1927)" as stated by the author]

H J O'D Burke-Gaffney

GLASGOW, J P & DUFFY, B J The Extermination of *Glossina palpalis fuscipes*, Newstead, by Hand Catching *Bull Entom Res* 1947, Dec, v 38, Pt 3, 465-77, 2 maps & 5 figs on 1 pl

The paper describes a successful eradication of *G palpalis* from a narrow water-side fly belt, by catching with nets

The authors worked on the river Sari in South Kavirondo, Kenya. About sixteen miles of river was infested with *G palpalis* They isolated two stretches of river-side vegetation by removing light bush, and used them for experiment and control The two stretches were thus isolated by clearings of 5 000 yards or over In one area of infested bush (3,800 yards long, about fifteen yards wide on each bank), fly-rounds were carried out for three months, and showed about sixty "total flies per 10,000 yards" Then ten teams of fly boys (three in each team, with a hessian screen) were brought in to catch flies this is equivalent to two teams per 1,000 yards of stream In the first six months they caught 282, 84 and 33, 2, 4 and 1 Meanwhile the standardized fly-round figure fell from about sixty to six or lower from the first month of catching Further study, including intensive attempts to catch flies, repeatedly showed no evidence of reinfestation up to seventeen months

Meanwhile in the other isolated stretch of fly-bush, where catching had not been undertaken, *G palpalis* continued to be common

Investigations were also carried out in the area in which SYMES and VANE [see this *Bulletin*, 1937, v 34, 542] carried out the first "catching out" experiment which had appeared successful and seemed to have controlled human trypanosomiasis. These areas had only been isolated by riverside clearings of about 1,000 yards Reinfestation had occurred, though the density of the flies was very low [which seems to suggest a recent reinvansion]

Blood-induced infections. Sulphadiazine only was used in prophylactic experiments administration spread over four days was again more effective than a more intense medication, as judged by the number of parasitized red cells present on the fifth day. It was doubtful whether sterilization occurred with this drug its action on blood forms and pre-erythrocytic forms appeared to be about the same. The four-day treatment as generally employed appears, on the whole, to have distinct advantages. *J D Fulton*

RIMINGTON C. & FULTON J. D. with the assistance of H. SHEDDEN. The Pigment of the Malarial Parasites *Plasmodium knowlesi* and *Plasmodium gallinaceum*. *Biochem. J.* 1947 v. 41 No. 4 619-22, 5 figs. on 1 pl. [16 refs.]

1 The pigment of malarial parasites (*P. knowlesi* and *P. gallinaceum*) has been extracted by a technique which avoids the use of alkali at all stages.

"2. From this material, crystalline haem and pyridine haemochromogen have been prepared.

3 A comparison of the spectral absorption of malarial pigment and of haemin in different solvents and of the visible bands and Soret bands of haemoglobin derivatives made by combining these pigments with renatured or globin confirms the identity of both malarial pigments with haematin (ferriprotophyrin)."

VANDERPLANK, F. L. Some Observations on the Hunger-Cycle of the Tsetse-Flies *Glossina swynnertonii* and *G. pallidipes* (Diptera) in the Field. *Bull. Entom. Res.* 1947 Dec. v. 38, Pt. 3 431-8, 1 fig.

The author wishes to know whether the interval between a tsetse's successive meals is longer at one season than another.

The method used is to estimate the hunger stage of the live fly. Those males which are captured in stage 1 (replete, recently fed) or stage 4 (very hungry) are marked with distinctive spots of paint the tip of the proboscis is snipped off to prevent further feeding and the insect is released. On subsequent days a considerable proportion of marked flies are recaptured and the hunger stage which they have reached is recorded.

The type of result obtained may be illustrated by the results with *G. swynnertonii* for December. Of flies released in stage 4 (very hungry) fifteen were recovered in the two subsequent days and none later. Flies released in stage 1 (replete) had reached stage 4 when recaptured between the 4th and 11th day (mean 7.35 days 23 individuals). From data of this type the author concludes that at that season, flies released when very hungry and unable to feed, carry reserves of food and water sufficient for two days or less. Those which were replete did not require to search for food for a number of days, and were therefore recaptured after about a week.

The paper contains similar data for *G. swynnertonii* for eight successive months, with monthly data on wind velocity saturation deficiency and evaporation also for *G. pallidipes* on a less extensive scale. It is conclusively shown that the mean hunger cycle of both species varies with season, is significantly correlated with measurements of humidity and is shorter when humidity is low or evaporation high. Under the conditions which prevailed, seasonal differences in temperatures were slight and without appreciable effect on hunger

was used and the injection was made up to 15 to 20 ml by the addition of normal saline, this was given very slowly. Most patients had paroxysms of coughing, leading to vomiting in a few instances, and one patient developed toxic jaundice two days after the injections. One developed pneumonia as a complication.

Three patients were Indian seamen and three were Englishmen who had served in India during the War. The three Indians responded well to treatment and were apparently cured but were not followed up. Of the three Englishmen, one was cured with a single course; he was known to be well five months later, one responded well to the treatment, but within three months the symptoms recurred and he still had leishmania in his sternal puncture material, he was apparently cured by a second course. The third was quite unaffected by the treatment; he was subsequently successfully treated with pentamidine.

The authors conclude that, although the treatment does not compare with that by neostibosan, urea stibamine, or the diamidines, where a rapid course is required and cost is an important consideration, this treatment might be recommended, since this course occupies two days only against 8, 30, and 12 days, respectively, and the cost is less than that of any of them. *L E Napier*

NAPIER, L E Intensive Treatment of Kala-Azar with Sodium Antimonyl Tartrate [Correspondence] *Lancet* 1947, Dec 20, 928

In a letter to the *Lancet*, referring to a paper by ADAMS and SEATON see above, the reviewer pointed out that he had used sodium antimonyl tartrate in the treatment of leishmaniasis since 1917, until 1923 almost exclusively, since there was no better drug available. For the relatively high mortality, which was the rule among patients under treatment for kala azar in those years, sodium antimony tartrate could not be exonerated from responsibility. If therefore experiments were to be made in concentrating the course of treatment he thought that one of the benign pentavalent compounds should be chosen rather than this relatively toxic trivalent salt. The only justification for the choice of sodium antimony tartrate was its extremely low cost. *L E Napier*

GOLDMAN, L Types of American Cutaneous Leishmaniasis—Dermatological Aspects A Review *Amer J Trop Med* 1947, Sept, v 27, No 5, 561-84, 12 figs [33 refs]

Cutaneous leishmaniasis is a disease of some importance to North American dermatologists on account of the frequency with which isolated cases appear at dermatological centres, and also because it exhibits certain features of special interest to those studying the immuno-biology of the skin.

The development of cutaneous leishmaniasis can be expressed as follows —

Inoculation → papule → ulcer → scar

A simple general classification for primary American cutaneous leishmaniasis is —

I Cutaneous II Mucosal, (a) primary, (b) metastatic III Mixed

The author, however, prefers Rabello's classification —

I Cutaneous

A Ulcerative (i) impetiginoid, (ii) ecthymatoid, (iii) true ulcer

B Non-ulcerative (i) nodular dermal, (ii) vegetant, (a) framboesoid or (b) verrucose

In conclusion, the authors emphasize that hand-catching speedily reduces *G. palpals* to a low figure, and would therefore be expected to check an epidemic. They state that it is much cheaper than clearing [It is essential to give cost in money and man days, in describing work of this type, and to state what items are included or excluded from the figures. The authors refer several times to cheapness in a purely qualitative way] P. A. Buxton

LEISHMANIASIS

HEILIG R. & SACHDEV R. N. Kala-Azar in Jaipur *Indian Med Gaz.* 1947 June 82, No. 6 336-9

It is generally agreed that the incidence of kala azar which is high in Eastern India, declines rapidly as one traces its extension westwards, but authors show differences of opinion on its westerly limit. Jaipur is in any case outside the recognized endemic area.

The authors report nine cases and claim that their report "confirms the experience that wherever one looks for kala-azar one shall find some. The cases were selected on account of positive aldehyde tests and enlarged spleens.

In two cases, leishmaniae were found by sternal puncture. In a third the sternal-puncture findings were doubtful and in three others negative. In the doubtful case and in two of the three negative cases, there was strong clinical evidence, including response to antimony to support the diagnosis of kala azar. However each of these five patients, in whom there was unequivocal or strong evidence of kala azar had lived at some time in a recognized endemic area: three within a year of one eighteen months before and one seven years before coming under observation. The last two were the patients in whom leishmania were found. Of the other four patients, in whom the evidence was limited to a large spleen and liver and a ++ aldehyde reaction, three had never left Jaipur and one was a nomad.

The authors conclude: "We are unable therefore, to make a definite statement whether kala azar of undoubted Jaipur origin exists, being not sure whether a fully positive aldehyde test, not corroborated by the presence of Leishman-Donovan bodies in sternal smears, is sufficient for establishing this diagnosis.

[The aldehyde test is of great value in a highly endemic area, especially for out-patient use when large numbers of patients are involved, and in these circumstances a definite positive reaction is sufficiently strong evidence for treatment to be undertaken. It is, however, a non-specific test and the diagnosis should always be confirmed by the demonstration of leishmania if data are to be used for scientific purposes, e.g. appraising the value of a specific drug or upsetting preconceived ideas regarding the geographical distribution of the disease.] L. E. Napier

ADAMS, A. R. D. & SEATON D. R. Intensive Treatment of Kala-Azar with Sodium Antimonyl Tartrate. *Lancet.* 1947 Oct. 18, 575-8.

Encouraged by the success of ALVES and BLAIR [this *Bulletin* 1946, v. 43 344] with intensive administration of sodium antimonyl tartrate in the treatment of schistosomiasis, the authors decided to try this treatment in six cases of kala azar.

Sodium antimonyl tartrate was given intravenously. The total dosage was about 1 grain per 12 lb. of body weight, divided into six doses given over a period of two days usually at 9 a.m., noon and 3 p.m. A 2 per cent. solution

CHEVE, J, COURDURIER, J & SAISSAC, R Typhus de laboratoire Intérêt des épreuves de contrôle pour le diagnostic des maladies inapparentes [Laboratory Typhus The Use of Control Tests for the Diagnosis of Inapparent Attacks] *Bull Soc Path Exot* 1947, v 40, Nos 9/10, 315-16.

Among 60 laboratory workers exposed every day to risk of infection, 12 suffered from recognizable attacks which were confirmed by Giroud's intradermal reaction and by rickettsia-agglutination tests Four inapparent attacks were detected by the same means

All the workers had been protected by the Durand-Giroud vaccine Rickettsiae could not be recovered from any of the patients *John W D Megaw*

FERRO-LUZZI, G & FERRO-LUZZI, S Therapeutic Study on Louse Borne Typhus *Boll Soc Ital di Med e Igiene Trop* (Sez Eritrea) 1947, v 7, Nos 1/2, 5-23, 2 figs [25 refs]

The authors have carried out tests of 17 special methods of treatment of typhus fever, of which they have observed 2,480 cases in a hospital in Eritrea during a period of about eight years commencing in February, 1939, half of the patients were employed as controls

The treatments tested included most of those for which claims of efficacy have been made, but they did not include *para*-aminobenzoic acid, which was not available

No significant benefit was observed except in the case of aspirin which was given in divided doses amounting to 4.0 to 8.0 gm daily

Among 95 patients treated with the drug only two died, and one of these was moribund on admission The fatality rate among the controls was 14.8 per cent The average duration of the fever among the treated was 11.1 days; among the controls it was 14.8 days Complications and untoward effects among the treated were 23.8 per cent, and 20.2 per cent among the controls A striking improvement is said to have occurred in nearly all the treated patients soon after the commencement of the treatment

[In view of many disappointments in the past, it is necessary to subject the methods of control to a close scrutiny, on this point the evidence supplied in the paper is incomplete and conflicting]

It is stated that "As far as possible the treatments were tried in alternate cases", but a little later the authors mention that selection of cases for treatment was governed "by the two following criteria, early stage of illness and high degree of severity" It also appears that the same group of patients formed the controls for tests of aspirin and three other drugs Detailed information is given of only two groups of patients, those receiving 4.0 gm aspirin daily, and those receiving 8.0 gm daily, from this it appears that in the former group, consisting of 40 patients, only one was over 30 years old and in the latter, consisting of 55 patients, no less than 20 were over 30

In view of the above evidence, the method of control cannot be regarded as satisfactory, and as aspirin was the last method tested it seems possible that the drug was tried towards the end of the epidemic season, though the authors state that the average severity of the attacks was much the same in the first as in the second half of the epidemic period during which aspirin was tested]

John W D Megaw

- II Subcutaneous ("pro parte")
 - A. Non-ulcerative
 - B. Secondary ulcerative
- III Mucosal
 - A. Vegetant—non-ulcerative
 - B. Vegetative—ulcerative
- IV Mixed various combinations of above.

The special character of American cutaneous leishmaniasis is mucosal involvement. This is of two types, primary or by direct extension from a cutaneous lesion and metastatic. The mucosal lesion does not occur in Mexico, it is uncommon in Costa Rica, but common in Peru. Extensive lesions resulting from neglect of early metastatic mucosal infections are common in adults, in contrast to the cutaneous lesions which are commoner in children over the age of six months. Weiss gives the frequency of mucosal involvement in Peru as from 20 to 80 per cent. according to the region. Mucosal lesions are usually in the respiratory tract especially the nasal septum.

Clinical diagnosis is always difficult. The location of the lesion on an exposed part of the body the chronicity and the response to antimony treatment help clinical diagnosis. In differential diagnosis gummata, chronic pyodermitis of the tropical ulcer type cutaneous diphtheria, artefactual lesions, and the infectious granulomata have to be taken into consideration. The last-named includes sporotrichosis, blastomycosis, chromoblastomycosis, paracoccidioidomycosis, yaws, syphilis granuloma inguinale [granuloma venereum] rhinoscleroma lupus vulgaris leprosy and stasis syndrome.

Parasitological diagnosis is also difficult. Smears are best obtained by pipette aspiration at the periphery of the lesion. Culture on N.N.N. medium can also be obtained by this procedure. Casual scraping of the lesion is useless. Histological study of biopsy material is of little value—non-specific inflammatory and tuberculous reactions are observed, and only rarely are intracellular parasites identified by this means.

The author discusses the inter-relationship between Old World and New World cutaneous leishmaniasis or visceral leishmaniasis and the factors which bring about the variations in the clinical types of American leishmaniasis. These include virulence of the organism, vector relationships, tropism secondary infections and natural and acquired constitutional factors. He considers that there are great opportunities for investigation in this direction.

Treatment is reviewed, but no special recommendations are made and there is a paragraph on prevention.

It is a stimulating article, if somewhat untidy and quite inconclusive. It should be read in the original by those especially interested in this disease.

There are a large number of excellent photographs illustrating the types of cutaneous leishmaniasis and the conditions from which it must be distinguished.

NELIS, P. La prophylaxie du typhus exanthématique en Belgique de 1940 à 1946. [The Prophylaxis of Exanthematic Typhus in Belgium from 1940 to 1946.] *Arch. Belges Méd. Sociale Hyg. Méd. du Travail et Méd. Légale*. 1946 Aug. 4 No. 6 298-315.

The interest of this article is chiefly historical. The systematic application of effective methods of control was remarkably successful in preventing any serious outbreaks of typhus fever in Belgium in spite of the repatriation of 284,000 Belgians from Germany and the passage through the country of a large number of persons of other nationalities who also came from Germany.

The total number of cases in 1944 was 10 of which 7 occurred in one infected focus. In 1945 there were 140 cases, but no less than 133 of the patients arrived in Belgium within the incubation period of the disease.

The author claims that the chief lesson to be learned from the success of the preventive measures adopted is the supreme importance of an organization based on a fully staffed and well-equipped laboratory. *John W. D. Megees*

FLOCH H. & CAMAIN R. Sur les fièvres typhoexanthématiques en Guyane Française. [Typhus Fevers in French Guiana.] *Institut Pasteur de la Guyane et du Territoire de l'Inini*. Publication No. 136 1947 July 4 pp.

In reporting a case of fever of the typhus group in 1941 (Publication No. 10 March 1941) the authors, working in the Pasteur Institute of French Guiana, concluded that these fevers did not constitute a simple problem in Guiana. They have therefore carried out systematic Weil-Felix tests from 1940 to the early part of 1943 on 3,732 sera submitted to the Pasteur Institute mostly for sero-diagnosis for syphilis and on 699 sera sent for Widal reactions.

The suspensions tested were *Proteus* OX19 Mets and Syria and Kingsbury H. and O. The first 2,438 of the 3,732 sera tested at a dilution of 1/50 gave 99 (4 per cent.) positive results the remaining 1,294 at 1/100 gave 29 (2 per cent.) there were thus 128 (3 per cent.) positives by these criteria.

High titres were rare and the positive results fell into two groups, namely those in which agglutination occurred with *Proteus* Mets and Syria only and those in which agglutination with the Kingsbury variants also occurred. The first group constituted 57 per cent. and the second 43 per cent. of all positive findings.

Among the 699 sera sent for Widal reactions, in febrile patients, 25 (4 per cent.) agglutinated the various *Proteus* suspensions at a titre of 1/100 this is about twice the percentage which was found in the case of sera of non-febrile patients.

The authors then describe a case of fever in a European aged 30 which clinically resembled one of the typhus group. All the agglutination tests were negative, except that against the Syrian strain of *Proteus* OX19 which was positive 1/300. The authors therefore examined the patient's serum further by the rickettsia agglutination technique of Giroud, with formalinized suspensions of murine and epidemic strains. This test was positive 1/5,000 with the murine and 1/2,000 with the epidemic strain a later specimen examined by Dr Giroud gave titres of 1/2,560 (and 1/5 120 \pm) for the murine and 1/300 (and 1/340 \pm) for the epidemic strain.

Many rats were found in broad daylight in the patient's house especially in the kitchen. The authors therefore confirm that murine typhus exists in French Guiana, especially in Cayenne, and that another fever of the typhus group, possibly tick borne is also present. *H. J. O'D. Burke-Gaffney*

- RAYNAL, J H Le chat dans l'épidémiologie du typhus exanthématique murin [The Cat in the Epidemiology of Murine Typhus Fever] *Bull Soc Path Exot* 1947, v 40, Nos 9/10, 367-75 [13 refs]

Murine typhus infection was detected in three out of 25 cats examined in Shanghai during 1942, which was a year of exceptional prevalence of typhus fever among the human and rat population

The author suspects that human beings who come into close association with cats may occasionally become infected through contact with dried faeces of infected fleas harboured by the cats. He thinks, however, that in ordinary conditions cats help to control infection by keeping down the rat population

- SOUTHCOTT, R V Observations on the Epidemiology of Tsutsugamushi Disease in North Queensland *Med J Australia* 1947, Oct 11, v 11, No 15, 441-50, 5 figs [15 refs]

Early in this paper, the author states that it is generally accepted that a diagnosis of tsutsugamushi disease should be based on the agglutination of *Proteus OXK* at a titre of 1-160 or, if this level should not be reached, on a rising-titre agglutination [but see the next abstract]

An opportunity occurred of investigating the incubation period of the disease in the Atherton Tableland and the adjoining coastal area of North Queensland. In 34 cases, the date of infection was ascertained, in 26 of these the incubation period was 11-13 days, in the remaining 8 cases it was 14-18 days. The author concludes that in Australia the period is of the order of 13 ± 2 days.

The effectiveness of dibutyl phthalate as a preventive was strongly suggested by the distribution of the eschars, nearly all of which were on parts of the body not adequately protected by the treated clothing. One of the three cases of typhus seen in the coastal area north of Cairns was diagnosed as North Queensland Tick Typhus.

Evidence was found supporting the view that birds are important in spreading larval mites, and that lizards, in the Cairns region, are a major factor in maintaining the population of the vector mites.

YELLOW FEVER

STEFANOPOULO, M. G. J. & DUVOLON, S. Mlle. Sur l'utilisation du cobaye dans l'étude expérimentale du virus de la fièvre jaune et en particulier du virus atténué de culture (souche 17 D). [Use of the Guinea pig in the Study of Yellow Fever Virus, especially Attenuated Strains.] *Bull. Soc. Path. Exot.* 1947 v 40 Nos. 7/8, 285-94 7 text figs. & 4 figs. on 2 pls. [15 refs.]

During the recent war the authors undertook this study of the effect of various strains of yellow fever virus in the guinea pig because of the scarcity of monkeys which are commonly used in testing the neurotropic properties of batches of yellow fever vaccine.

It was found that the attenuated 17D virus (used for vaccine) killed about 40 per cent of guineapigs when inoculated intracerebrally, animals weighing less than 350 gm were more susceptible than heavier ones. Ten passages of the vaccine virus through mouse brain, followed by 7 to 16 passages in chick embryos, failed to increase the virulence of the virus. In addition to those animals which died, some developed paralysis and recovered and others had an inapparent infection which was detected either by reinoculation with virulent virus or by testing for neutralizing antibodies in the blood.

The histological lesions resembled those found after inoculation with the neurotropic strain of yellow fever, but the latter virus produced a more rapidly progressive illness with a mortality of nearly 100 per cent. Thus, the guineapig may be used to detect potential neurotropism of the attenuated 17D vaccine virus. However, the rhesus monkey remains the most suitable animal for this purpose, for it is also capable of detecting return of the attenuated virus to full viscerotropism.

HERRERA, G & PARDO, V. A New Method for Biopsy of the Liver. *Arch Pathology* 1947, Oct, v 44, No 4, 393-5, 1 fig

"A method of obtaining liver for biopsy is described which makes it possible to obtain a cylinder of tissue as long as the distance covered by the trocar in the liver and of the same thickness as the diameter of the trocar. A wire loop at the end of the trocar is an essential feature of the instrument.

"The trauma is minimal, abundant tissue is obtained in every case.

"We have obtained biopsy specimens from 72 patients without a single hemorrhage or other complication."

DE CAIRES, P F. DDT and *Aedes aegypti* Control in British Guiana. *Puerto Rico J Pub Health & Trop Med* 1947, June, v 22, No 4, 405-15, 5 figs [Spanish version 416-24]

British Guiana is the last place of call of northbound air and sea traffic from South America. The control of *Aedes aegypti* in the thickly populated coastal zone, as a yellow fever preventive measure, is rendered very difficult by the complex system of rainwater storage for drinking purposes. A controlled experiment on familiar lines was carried out to determine the efficacy of DDT applied as a residual insecticide. That the very domestic *Aedes aegypti* is most susceptible to 5 per cent DDT in kerosene is clearly demonstrated in that eradication of the species was attained 13 weeks after the single spraying, and maintained for 10 months. A 2½ per cent solution was less effective. It is believed that this method applied on a large scale will be more economical than routine anti-*aedes* measures of control. species in terms of infection potential, vector potential and transmission potential. According to Burroughs, the vector efficiency thus obtained represents only an approximation to natural efficiency and he points out that this is inevitable because ignorance of ecology precludes the duplication of natural conditions. He uses the well-known statistical formula $\bar{X} \pm K\alpha \sqrt{\frac{S^2}{N}}$ in order to

find the range within which the true value probably lies, "to estimate the expected number of mice killed (total number of daily transmissions) per flea where \bar{X} is the average number of transmissions per flea for the entire number of fleas studied, N the total number of fleas used in the studies," and α "the probability that the estimating interval covers the true value." In this way, it was found that the true vector efficiency, with a confidence of 90 per cent, of important fleas could be given as —*Xenopsylla cheopis* 0.660 ± 0.234 , *Nosopsyllus fasciatus* 0.213 ± 0.157 , *Orchopeas sexdentatus* 0.170 ± 0.138 , *Diamanus montanus* 0.02 ± 0.02 . The low value and inefficiency given to this last flea, which is grouped with *Opisodasys nesiotus*, *Megabothris abantis* and *Malariaeus telchinum*, is not supported by the work of WHEELER and DOUGLAS [loc cit] who regard it as an exceptionally good vector (0.840 ± 0.232) and more efficient than *X. cheopis*. This, it is suggested by Burroughs, may be due to a difference of strains collected in a widely separated geographical area.

Among the several conclusions is one of considerable interest, "The order of importance of transmission by fleas is the following (a) By the blocked flea serving as a biological vector (b) Mechanical transmission which undoubtedly is of considerable importance during an epizootic (c) By the infected flea or its faeces being scratched into the skin (d) By the ingestion of fleas harbouring plague bacilli. Infection by the latter two methods is undoubtedly rare and of minor importance."

HOPKINS, G H E. **Annotated and Illustrated Keys to the Known Fleas of East Africa**. Reprinted from *Uganda J* 1947, Sept, v 11, No 2 (Scientific Suppl.), 133-90, 146 figs on 21 pls [35 refs]

The species of fleas dealt with in this paper are those occurring in Kenya, Tanganyika, Uganda and Zanzibar. Rather less is known about the fleas of Tanganyika than of those of the other territories. With the exception of the common poultry flea (*Echinophaga gallinacea*), there seems to be an absence of indigenous bird fleas in spite of the fact that many nests have been examined.

The worker is urged, when using the keys, to have his provisional identifications checked by a specialist except in the case of the commonest fleas. Most of the characters used for identification are shown in a diagram and the important morphological details for distinguishing species are figured. In addition to the keys, there are notes on characters for separating closely related forms, on bionomics, the technique of collecting, preparation for study, preserving and on control. The index contains the names of 25 genera and over 80 names of species and subspecies.

MCDougall, W A. **An Investigation of the Rat Pest Problem in Queensland Canefields**. 5 Populations. *Queensland J Agric Sci* 1946, Dec, v 3, No 4, 157-237, 10 figs (1 map), & 3 pls [41 refs]

This monograph, the fifth of a series, is concerned largely with the trapping of rats, especially *Rattus conatus*, in estimating rat populations. It is largely of agricultural interest, but in discussing the influence of disease on population fluctuation in rats, the author notes that bubonic plague in Queensland in 1921-22 did not appear to have any effect on cane rat population trends at

The present study deals with the employment of the same treatment in a certain number of cases of dengue in East Africa, with similar happy results. Five charts are reproduced showing in each case a rapid fall of the temperature.

[Although the relief of symptoms by decompression is not surprising the complete arrest of the febrile process in a virus disease is truly remarkable. In view of the wide range of variation that is known to occur in the duration and severity of attacks of dengue, a fully controlled test of the treatment ought to be carried out. The author describes dengue as a fever lasting eight to nine days with two paroxysms of fever unbearable headache, and invariably followed by a long period of weakness and depression but short "one-phase" attacks and rapid recovery are common in certain outbreaks.]

PLAGUE

BURROUGHS, A. L. Sylvatic Plague Studies. The Vector Efficiency of Nine Species of Fleas compared with *Xenopsylla cheopis*. *J Hygiene* 1947 Aug., v 45 No. 3 371-88, 3 figs. on 2 pls. [59 refs.]

This study which has sylvatic plague as its background, is primarily concerned with an expression of the vector efficiency of the flea *Xenopsylla cheopis* is used as the basis of comparison. This flea and the domestic rodents, and not the wild rodent reservoir are considered to be the agents responsible for bringing plague into contact with human beings. The fleas studied were — *X cheopis* *Dramaeus montanus* *P irritans* *Oropsylla idahoensis* *Neopsyllus fasciatus* *Echidnophaga gallinacea* *Orchopeas saxatilis* *accidentatus* *Opiodarys nesiotes* *Megabothris aberti* *Malariaus telchium* and their hosts are noted.

In the United States, up to the present, only 66 cases of plague infection in man have been traced to sylvatic rodents. In the present paper in addition to the main subject matter that of numerical expression of vector efficiency there is a well-balanced historical recapitulation of our knowledge of plague bionomics. Much of this is based on the valuable accounts and documentation of the Indian Plague Research Commission. [It may be well to recollect that there was an earlier British Commission, a Royal Commission 1898-99 of which the medical members were Sir Thos. Fraser, Sir Almaroth Wright and Armand Ruffer.]

A great deal of preliminary work on the rat and rat flea was done before the main plague Commission got to work. References are made in the present communication to the experimental establishment of the fact of mass transmission experiments from rat to rat by fleas (Simond, 1898) to Liston's work on the relationship between rat fleas and man (the first public communication of which is recorded in the *Transactions of the Bombay Medical and Physical Society* February 1903) and, possibly more dramatic, the demonstration in 1903 of plague bacilli in the proventriculus of the rat flea fed on infective blood to the conclusion of the Plague Commission (1906) that transmission of infection by a single flea was only remotely possible. Many other facts of the history of plague are brought to mind in the article, such as the comparison of the efficiency of *X cheopis* and *X astia* the check on the advance of an epidemic when the mean daily temperature attains 80°F if accompanied by a saturation deficiency (Brooks 1917) of over 0.3 m. that classical work, the first demonstration by Bacot and Martin (1914) of proventricular block by plague bacilli in the rat flea the distinction between pestiferous and pestiliferous fleas, and so on.

We may leave this interesting historical account and proceed to the subject matter proper. WHEELER & DOUGLAS [this Bulletin 1946 v 43, 35] presented an experimental method of measuring numerically the vector efficiency of a flea

species in terms of infection potential vector potential and transmission potential. According to Burroughs the vector efficiency thus obtained represents an approximation to natural efficiency and he points out that this is inevitable because ignorance of ecology precludes the duplication of natural conditions. He uses the well-known statistical formula $\bar{X} \pm K\alpha\sqrt{\frac{S^2}{N}}$ in order to

find the range within which the true value probably lies, "to estimate the expected number of mice killed (total number of daily transmissions) per flea where \bar{X} is the average number of transmissions per flea for the entire number of fleas studied, N the total number of fleas used in the studies" and α 'the probability that the estimating interval covers the true value'. In this way, it was found that the true vector efficiency, with a confidence of 90 per cent, of important fleas could be given as — *Xenopsylla cheopis* 0.660 ± 0.234 , *Nosopsyllus fuscicollis* 0.213 ± 0.157 , *Orchopeus sexdentatus sexdentatus* 0.170 ± 0.138 , *Diamanus montanus* 0.02 ± 0.02 . The low value and inefficiency given to this last flea, which is grouped with *Opisodysus nesiotes*, *Megabothris abantis* and *Malaraeus telchinum*, is not supported by the work of WHEELER and DOUGLAS [*loc cit*] who regard it as an exceptionally good vector (0.840 ± 0.232) and more efficient than *X. cheopis*. This, it is suggested by Burroughs, may be due to a difference of strains collected in a widely separated geographical area.

Among the several conclusions is one of considerable interest, "The order of importance of transmission by fleas is the following (a) By the blocked flea serving as a biological vector (b) Mechanical transmission which undoubtedly is of considerable importance during an epizootic (c) By the infected flea or its faeces being scratched into the skin (d) By the ingestion of fleas harbouring plague bacilli. Infection by the latter two methods is undoubtedly rare and of minor importance."

WAGLE, P. M. & COLAH, R. B. M. Prognostic Significance of Leucocyte Count in Bubonic Plague. *Indian Med. Gaz.* 1947 July v 82, No. 7 399-402, 1 chart.

There were 446 cases of bubonic plague treated with sulphonamides, and analysis was made of the leucocytic reaction and its correlation with both septicaemia and death rate. All those suspected of showing the hyper or hypo-leucocytosis of toxic sulphonamide action were excluded from the series. Where more than one count was made on a patient, the highest result was used for the calculations. If a total count of 5,000 to 10,000 leucocytes per cmm. be taken as more or less normal level the curious fact emerged that this proved to be an optimum condition for prognosis—17.7 per cent. mortality for 79 cases. Three of 6 patients with a count of less than 5,000 died, and mortality in the opposite direction mounted steadily to 97.3 per cent. for a count of over 40,000. The authors think that the counts below the normal base level indicate lack of resistance, and above that level, the degree of reaction was highly correlated with degree of septicaemia. At the same time, septicaemia occurring with a normal leucocyte count was of grave prognosis and was, in fact, a manifestation of lack of resistance. The degree of septicaemia, which is the main factor determining the severity of plague infection, was determined by colony counts of drawn blood sown on agar slopes. Mortality rates of the 446 cases worked out at 7 per cent. for the non-septicaemic, 54.9 per cent. for the septicaemic, 21.8 per cent. for the mild septicaemic and 65.8 per cent. in severe cases.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

✓ ALKAN W Amoebiasis as seen during 18 Months with a Military Hospital. *Harefuah*, Jerusalem. 1947 Nov 2, v 33 No. 9 [In Hebrew 143-6 (13 refs.) English summary 148.]

The author describes 66 cases of amoebiasis seen in 18 months among 4,965 patients, mostly Indians in hospital in Greece and Italy. Dysenteric hepatic and cutaneous forms and the carrier state are reviewed. Many cases were easily mistaken for simple intestinal conditions: cysts were found in only 14 cases. The author advocates reasonable treatment of every patient infested with *E. histolytica* owing to the inherent danger of apparently inconspicuous infections, the absence of a sharp demarcation between infestation and infection and the apparent general increase in amoebiasis. All the usual diagnostic methods are recommended but treatment, on the whole, was not found to be quite satisfactory. The author finds emetine to be useful only in combating acute symptoms, but it was of value in the treatment of extra-intestinal complications. For the dysenteric form, the other recognized drugs are recommended. The psychological factor in treatment is of importance whatever form of treatment is adopted, relapses are common.

H J O'D Burke-Gaffney

CALVÓ FONSECA, R. La incidencia de la *E histolytica* en Cuba [The Incidence of *Entamoeba histolytica* Infection in Cuba] *Kuba Habana*. 1947, Oct, v 3, No 10, 220-24

The author reviews the findings which have been recorded by various investigators into the prevalence of infection by *E histolytica* in Cuba. As a result of examination of 38,091 specimens of faeces from persons in 6 Provinces and 126 Municipalities, the general incidence was found to be 2.2 per cent, with lower and upper limits of 0.31 and 6.74 per cent. Going into the question more thoroughly, the author studied the reports from various countries of South America and found that the methods employed varied widely, some examined one slide only, others more, some after a saline purge had been given, others not—in short, there was no uniformity and the results were, in consequence, not really comparable.

The author, therefore, proposed, and the Section of the Medical Congress held in December, 1946, supported, the resolution, that some standard should be adhered to, and four points were decided upon: (1) That the number of specimens should be more than one, if the first proved negative, and that, under these conditions, examination should be made after administration of a saline purge. (2) That the number of persons examined should be at least 2 per cent (better 5 per cent) of the population. (3) That, whether urban or rural, a fair cross-section of the social groups should be included and, for this purpose and to include both sexes, those attending school between the ages of 6 and 18 years would be best. (4) Method of examination: (i) The preparation should be a thin one, with physiological saline as diluent, (ii) another preparation should be examined, diluted with Lugol's iodine, (iii) a Gram-stained preparation for searching for protozoa and cysts should be made, (iv) a specimen should be examined by Faust's concentration method, as modified by OTTO, HEWITT and STRAHAN [this *Bulletin*, 1941, v 38, 473].

[This method may not find recommendation from all, but there is much to be said for some standard procedure in order that results reported by investigators in different countries can be compared.]

CONVERS, F. El examen radiológico en los abscesos amibianos del hígado [Radiology in (Diagnosis of) Amoebic Abscess of the Liver] *Rev Facul de Med Bogotá* 1947, June, v 15, No 12, 727-53, 31 figs

An interesting series of X-ray photographs showing the presence of liver abscess, with notes on each of eleven cases out of 50 which the author has had under his observation and care in Colombia. In all, the right lobe was involved, in many cases the X-rays established a suspected diagnosis, in others they revealed an abscess when there had been no suspicion of such. Injection of air, after puncture, the author found very useful in defining the limits of the abscesses. Eight of the cases noted were treated by puncture and administration of emetine, the other three showed enlargement of the liver, but in one only a small collection of pus, and the condition cleared up after administration of emetine, without operation.

MORTON, T. C. & SOUTAR, S. F. Amoebic Abscess of the Left Buttock in a Symptomless Cyst Carrier *Brit Med J* 1947, Dec 20, 996-7

A case of amoebic ulceration of the buttock in a symptomless cyst-carrier is described. The patient had previously been kicked on the same area during a football match so that there had been a local injury. About one and a half years later, a fluctuating swelling appeared containing pus infected with

heterophyid adult flukes in the feces of the same patient after a routine chenopodium treatment clinches this important finding. The patient died a year after of vascular accident resulting from the rupture of esophageal varices. Scrapings of the small intestines still showed heterophyid flukes thus confirming definitely our previous findings.

VON BOMSDORFF B. The Site of Infestation with Fish Tapeworm determined by means of Intestinal Intubation. *Diphyllobothrium latum* and Pernicious Anemia. *A Acta Med Scandinavica*. 1947 Nov 25 v 129 No. 3 213-33 9 figs. [10 refs.]

The author has recently discussed the question of localization of *Diphyllobothrium latum* in the human intestine, as a result of information amassed in replies to a questionnaire [see this *Bulletin* 1948, v 45 198].

He has now carried the matter a stage further by attempting to determine the point at which eggs or proglottides might be found by means of intestinal intubation and aspiration of intestinal contents.

The method employed is described and should be studied in the original it consisted of a modified duodenal tube it has certain disadvantages, which are discussed. The tests were made on tapeworm-carriers with and without pernicious tapeworm anaemia and comprised 28 persons. 10 had a normal blood picture 3 had "non-pernicious" anaemia 10 had manifest pernicious tapeworm anaemia and 3 had the last named condition in spontaneous remission.

The results are shown in a table in the text and full blood and clinical details are given in three other tables. From these, it can be seen that where pernicious T.A. was present the worm was in the jejunum (85-135 cm. from the mouth) while in non-anaemic persons, those with non-pernicious anaemia and those with remissions of pernicious T.A. the worm was not found before the ileum was reached (up to 334 cm.) It is suggested that when the worm is high up in the intestine, it has an opportunity of impairing the interaction between Castle's extrinsic and intrinsic factors, thus causing a pernicious anaemia [see this *Bulletin* 1947 v 44 1081]. H J O D Burke-Gaffney

HIRVONEN M. On the Differential Diagnosis between Pernicious Tapeworm Anemia and Cryptogenetic Pernicious Anemia in Carriers of *Diphyllobothrium latum*. *Ann. Med. Intern. Fenniae* 1947 v 36, Suppl. 2 30 pp. 29 figs.

The object of the work discussed in this careful and detailed monograph was to help in establishing the differential diagnosis between pernicious anaemia (P.A.) and severe tapeworm anaemia (T.A.) in carriers of *Diphyllobothrium latum* the question is of special importance in Finland where *D. latum* infection is common and an unjustified diagnosis of pernicious anaemia may involve a patient in a long, anxious and expensive course of unnecessary liver treatment, perhaps for the rest of his life.

The author establishes this differential diagnosis on the basis, firstly, of examining for free hydrochloric acid in the gastric juice its presence eliminates a diagnosis of P.A. but its absence does not necessarily help the diagnosis. The patient is then given worm cure as a first stage if he can stand it but if his Hb. percentage is below 25 and his red corpuscles below $1\frac{1}{2}$ million per cmm., this may prove to be dangerous unless liver treatment is first administered and in fact such a measure had a fatal result in two of the cases described. After the worm cure, blood regeneration should be studied microscopically if the blood picture becomes normal on worm cure alone, the case

is one of T.A., and may be so even if this regeneration ceases and only begins again after liver treatment. The pathology of this latter state is discussed and it is suggested that it may be an intermediary stage between T.A. and P.A. In doubtful cases, the differential diagnosis can only be established by prolonged re-examinations after liver treatment and apparent regeneration of the blood picture. If, on the other hand, the patient's blood state is too low or for other reasons he is too weak to have worm treatment as the first therapeutic measure, and no free HCl is present in the gastric juice, these same prolonged re-examinations are required. Finally, the author makes the important differential point that P.A. hardly ever appears before middle or old age.

The material for these investigations consisted of 34 cases of severe anaemia in *D. latum* infections. These are divided into 3 main groups: (1) the certain T.A., (2) the differentially uncertain, and (3) the certain P.A.

In group (1) there were 12 patients with free gastric HCl, although in three, and probably four, liver treatment was required in addition to worm cure before blood regeneration became complete. In this group were also 7 patients with no free gastric HCl who nevertheless recovered completely on worm cure alone.

In group (2) there were 5 patients without free gastric HCl who received liver treatment, but whose improvement was maintained even after this treatment was stopped. There were also 6 patients in whom the diagnosis was uncertain because after-examination was not practicable (in two cases, cited above, owing to death).

In group (3) there were 4 certain cases of cryptogenic P.A. all occurred in old people and continued liver therapy was necessary. The author considers that the removal of the worm was a side-issue in their treatment.

H. J. O'D. Burke-Gaffney

MAZZOTTI, L., RODRIGUEZ, L. & TREVIÑO, A. Observaciones en 161 personas parasitadas con *Taenia* [Remarks on 161 Cases of Taeniasis] *Rev. Inst. Salubridad y Enfermedades Trop.* Mexico 1947, June, v 8, No 2, 155-62. English summary (8 lines).

The authors, during the past three years, have had under observation 161 persons infested with *Taenia*, 141 with *T. saginata* alone, 16 with *T. solium* alone, and 4 with both species. One hundred and thirty received treatment, 15 of those with *T. solium*, all four of those with both infestations and 111 with *T. saginata* only. Most of the patients were in the third decade; the youngest was a girl of 2 years and the oldest was aged 70. In 10 of the *T. solium* cases, eggs were found in perianal smears and in 4 others on the body and on the underclothing. Ninety-five of the patients complained of "nervous disturbances," change of character, irritability, nausea and, rarely, paraesthesiae. 38 suffered from pruritus ani, 29 from abdominal pain.

Three forms of treatment were given, but, as preliminary to all, the patient was put on a semi-solid diet of cereals, gruel, eggs, soft fruits, etc. on the day before, a saline laxative the same evening, a warm water enema the next morning and, before any food was taken, the specific medicament, divided into three doses, was given at half-hour intervals and, 1½ hours later, a saline purge. The patients were divided into three groups. Group I, 59 patients, received ethereal extract of male fern. In 22 the scolex was found, in 37 it was not, but 4 of these did not relapse; this is regarded as a 44 per cent cure. A second group of 52 was given the oleoresin of male fern, 2-3.5 gm. to adults, 15 cgm. for each year of age to children, in three doses as before, in gelatin capsules. In 42 (80.7 per cent) the scolex was recovered. A third group of

19 were given pumpkin seeds. 300 gm. was the total dose, but as this was so large an extract was made with sulphuric ether to remove fats and a watery extract made of the residue, the total dose being 125 cc. In three the scolex was recovered, from 16 it was not, but 7 of the latter did not relapse, the result being reported as 53 per cent. cure. The fact of the ova of *T. solium* being found on the body and underclothes may explain some of the cases of human cysticercosis.

H. Harold Scott

HOOD M. The Present Status of Hookworm Infection in Florida. *Amer J Trop Med* 1947 July v 27 No. 4 505-16 3 charts & 1 fig. [18 refs.]

The importance of hookworm infection as a medical problem in Florida was recognized in 1903. Hookworm campaigns and surveys have been repeatedly undertaken since that date. The first survey undertaken under the auspices of the Rockefeller Foundation in 1910 showed that 58.1 per cent. of 6153 persons examined had hookworm infection. In 1926, another survey showed a 56.2 per cent. infection rate. It was at one time assumed that infection and disease were synonymous, but later by employing counting methods, SMILLIE and AUGUSTINE [this *Bulletin* 1926 v 23 772] showed that only heavy (12,600 and over eggs per ml.) and moderately heavy (2,600-12,599) infections were clinically significant. Persons with light (700-2,599) and very light (200-699) infections did not improve in health significantly after anthelmintic treatment, while those with heavy infections did. A third survey, in 1937-38 undertaken by a Vanderbilt group [*ibid* 1939 v 36 823], showed a 34.8 per cent. infection of 29,064 specimens of these 11.5 per cent. were classed as moderate or heavy infections.

For the present survey the zinc sulphate concentration method was used to detect infections and also for estimating intensity. Parallel egg counts by the Stoll and zinc sulphate techniques were made in order to establish a ratio, as it was shown that 1 to 40 eggs per cover-glass constituted a very light infection, 41 to 150 a light, 151 to 700 a moderate, and 701 and over heavy infection.

A study of 8,017 white school children showed a marked variation between the counties in both incidence and intensity of infection. Approximately 40 per cent. of the white children have hookworm infection but only 3.9 per cent. of the whole number or 10 per cent. of the positive cases, are classed in the moderate and heavy intensity groups.

Very low incidence and intensity of hookworm infection are shown in a group of 1,264 coloured children studied (13.3 per cent. positive).

Hookworm infection is most marked during school age. A sharp diminution in both incidence and intensity is shown about the twentieth year.

Both incidence and intensity of hookworm infection are greater in the western section than in any other area of the State.

It is considered that, although there has obviously been a great reduction in the hookworm incidence in Florida, it is still a public health problem. It is believed that better results will be obtained in anti-hookworm campaigns if all infections are reported according to their intensity so that efforts can be concentrated on groups that show the largest number of moderate and heavy infections.

HERNÁNDEZ LIRA, J. P. Aspecto mexicano en relación con la clínica y el tratamiento de la anquilostomiasis. [Ankylostomiasis in Mexico.] *Medicina*. Mexico. 1947 Nov 10 v 27 No. 543 481-83.

After general remarks on the history of ankylostomiasis and its symptomatology the author speaks in detail of the methods of treatment used in Mexico.

He mentions various drugs which have been tried from time to time and states that several "accidents" have occurred after administration of oil of chenopodium and of carbon tetrachloride, and in consequence the latter has been discarded altogether, and at the present time only three drugs are used, namely, oil of chenopodium (with 76 per cent ascaridole) hexylresorcinol, and tetrachlorethylene. The first is specially serviceable because *Ascaris* infestation often accompanies that with hookworm. To children of 3-4 years of age 0.1 cc is given, of 5-6 years 0.15 cc, and 7-8 years 0.20 cc, with a purge of castor oil. To those above this age the drug is given in capsules (dosage is graded, adults of 20 years or over receiving 1.25 cc) and a saline purge is given one hour later. Patients are examined before treatment is given to find out if there are any contraindications. The drug is given before any food is taken and the patient is kept under observation for 2-3 hours for any signs of absorption. *Hexylresorcinol* is given as chocolate-coated pills of 0.2 gm each, in doses of 0.07 gm per year of age, so children of 6 years are given two pills, or 0.4 gm, of 6-8 years three pills, 8-12 years four pills, and those over 12 years five pills or 1.0 gm. No food is allowed for four hours afterwards and a saline purge is usually given. Tetrachlorethylene [the formula is wrongly given as Cl_2C_2 , instead of C_2Cl_4] is administered to adults in amounts of 2 cc in divided doses (3 cc may be given to powerful adults without harm and proportional doses to younger subjects) followed by a purge of sodium sulphate. If ova were found a week later the dose was repeated. Of 458 patients so treated, 11 per cent were cured after one treatment, 16 per cent after two, 27 per cent after three, 40 per cent after four and 98 per cent after five treatments. In all cases, the patients are kept under observation and the anaemia consequent on the infestation is treated with iron preparations.

H Harold Scott

GUEVARA, R. Toxicity of Oil of Chenopodium when administered together with Castor Oil. *J Philippine Med Ass* 1947, June, v 23, No 6, 259-67 [15 refs]

Oil of chenopodium is a well-recognized anthelmintic. Its active principle is ascaridol, and it is used in the treatment of *Ascaris* and hookworm infections. In ordinary doses it paralyzes but does not kill the worms, it is therefore necessary to follow the administration of this drug by a purgative. It is convenient to give this purgative at the same time as the drug. Castor oil is often used as the purgative. The combined administration is usually looked upon as a safe procedure, but in the Philippines a prejudice has arisen against giving castor oil with oil of chenopodium. It is thought that this is because a popular mixture containing oil of chenopodium and castor oil has given rise to toxic symptoms and in some cases death. There are, however, other ingredients in this mixture.

An investigation was undertaken to prove or disprove the theory that castor oil increases the toxicity of oil of chenopodium. Cats, twenty-seven in all, were used as experimental animals. With a dose of oil of chenopodium of 0.20 ml per kilogramme, all the cats died, with a dose of 0.1 ml all survived, and with a dose of 0.15 ml one died and two survived. When 15 ml of castor oil was added to each dose of oil of chenopodium, all cats survived doses up to 0.30 ml, one out of three survived 0.35 ml and all three died with doses of 0.40.

The author concludes that the addition of castor oil halves the toxicity of oil of chenopodium rather than increases it, and that, as there are more advantages in taking the combined drugs than each drug separately, this procedure should always be followed.

The symptoms of toxicity were vomiting, general muscular weakness, prostration, ataxia convulsions, stupor coma and death, convulsions being the most prominent and lasting several days prior to death. L. E. N. *post*

GUTMAN F & MORALEZ, P. Ascaris in the Cerebral Bile Duct. (A Report of 10 Cases) *J Philippine Med. Ass.* 1946, July v 22, No. 7 299-303.

GALLIARD H. Evolution de *Wuchereria bancrofti* et *W. malayi* chez *Aedes* (*Stegomyia*) *aegypti* et *A. (S.) albopictus*. [Development of *Wuchereria bancrofti* and *W. malayi* in *Aedes aegypti* and *Aedes albopictus*.] *Ann. Parasit. Humains et Comparés.* 1947 v 22, Nos. 1/2 30-35.

Complete development of *Wuchereria bancrofti* in *Aedes aegypti* was demonstrated in certain cases, while in others the development was partial only or abortive. Early larval stages only were found in *Aedes albopictus*.

Complete development of *W. malayi* was observed in a small percentage of cases in both species of mosquitoes. J J C Buckley

ROCKES, L. The Present Position of Antimony Treatment of Filariasis: with a Suggestion for its Intensive Use. *Indian Med Gaz.* 1947 June, v 82, No. 6 348-8.

Recent work in filariasis at Porto Rico confirms the author's observations made in 1919-1920 regarding the effect of antimony in this infection.

After Christopherson's observations on the effect of sodium antimonyl tartrate in schistosomiasis the author carried out preliminary investigations at Puna and later at Caticlat jail. In the latter investigation, eight persons with high microfilaria counts average 73 per 20 cm. [200 mm.] were chosen and treated with sodium antimonyl tartrate with doses up to 5 ml. of a 2 per cent. solution intravenously. In four cases, the microfilaria counts fell steadily for 3 months after the cessation of treatment, reaching 3 to 9 per cent. of their original number whereas in four others after an early fall in the counts, every month there was a sharp rise which brought the microfilaria curve back to the original level. These peaks were due to the sudden appearance of young embryos, easily distinguished from older forms. The author concluded that, in the first four cases, the adult worms had been killed or very seriously damaged.

These observations were confirmed by DAS in India [1920] DAY in Egypt [Lancet 1921 Mar 12, 525] ROY & BOSE [Indian Med Gaz. 1922, v 57 231] and BAR in the Dutch East Indies [no reference]. These workers also showed that the repeated attacks of febrile lymphangitis were eliminated or reduced in frequency and that in cases of elephantiasis there was a reduction in the diameter of the limbs after 2 to 5 doses of sodium antimonyl tartrate. These observations were not confirmed by the British Guiana Filariasis Commission under Liper [Leprie].

In 1943 Professor Culbertson of New York [CULBERTSON ROSE & OLIVER-GONZÁLEZ, this Bulletin 1946 v 43 354] showed that antimony killed the adult filariae in the pleural cavity of cotton rats, but that the microfilariae continued to circulate in the blood for many months and that the drug had a similar effect in man if the cases were followed long enough. Some of their cases were followed for 3 years. The best results were obtained with neostibosan, given in intensive doses up to totals of 15 grammes. With small doses of tartar emetic, average total 0.79 grammes, reductions to 41 to 6 per cent. of the original microfilaria counts were obtained.

The author concludes that neostibosan is the drug of choice, but considers that it may prove too expensive in the endemic areas, and suggests that intensive treatment by sodium antimonyl tartrate as used by ALVES & BLAIR [this *Bulletin*, 1946, v 43, 344] in schistosomiasis, might be as effective in filariasis

RUIZ REYES, F Tratamiento experimental en la oncocercosis con el "Naphuride Sodium" [Naphuride Sodium in the Treatment of Onchocerciasis] *Medicina Mexico* 1947, Oct 25, v 27, No 542, 475-7

[If more investigators had the courage to report negative results, we would hear less of the success of remedies vaunted on one or two beneficial effects] The author, at the request of Dr CULBERTSON of the University of Arkansas, has taken up anew the subject of this drug and its action in onchocerciasis. Naphuride sodium, a product of the Winthrop laboratories, is a synonym of Germanin, Bayer 205, Moranyl, 309 Fournneau and Naganol. The author has tried it in five cases of onchocerciasis of 10-15 years' standing, with abundant embryos in the skin, and two of the patients are blind. Each was given 1 gm in 10 cc of doubly distilled water intravenously once a week for five weeks. The weights of the patients ranged between 38 and 50 kgm, and their ages between 16 and 62 years. The drug caused headache, nausea, vomiting and occasionally "severe nephritis," but early examination of the urine (2 days after each dose) forestalled any untoward effects [so says the author, who evidently does not regard severe nephritis as such an effect]. The results on the infestations were controlled by frequent biopsy examinations of the skin to determine whether the embryos were killed by the drug. A table gives the detailed results of the many biopsies and the only conclusion which can be drawn is that "Naphuride Sodium has no obvious effect on onchocerciasis when given by the method described in this article"

H Harold Scott

BERTRAM, D S The Period required by *Litomosoides carini* to reach the Infective Stage in *Liponyssus bacoti*, and the Duration of the Mites' Infectivity *Ann Trop Med & Parasit* 1947, Sept, v 41, No 2, 253-61

Three series of mites were infected and maintained on cotton rats and on white rats by methods previously described. By these methods, the date on which the mites first become infected is known within a limit of twenty-four hours. An account is given of present experiments and the following is the author's summary —

"It is concluded that white rats and cotton rats which become positive for *L. carini* after serving as hosts to infected female *L. bacoti* are infected by the transmission of the active thread-like worm larvae which develop in the mites. Transmission appears to occur in association with the feeding habits of the mite but the actual mode of transmission is not known, and other methods of transmission by the mite cannot be discounted.

"Infected mites stored at 23-25°C and maintained by blood-meals at approximately five-day intervals first transmit the infection of *L. carini* to white rat and cotton rat hosts on the occasion of the third meal, or the 15th day, after the mites' infecting meal. Transmission continues until the fifth meal on the 25th day, possibly with diminishing intensity, and it may occur until later than the seventh meal or the 36th day after the mites infecting meal.

"Of two cotton rats exposed to infection by 17-30 mites of a series in which 38 per cent were positive, one rat which was exposed for 24 hours on the 15th

day after the mites infecting meal developed an infection averaging 273 mf./cmm. of peripheral blood (range 90-870 mf./cmm.) in 20 weekly counts the other rat which was exposed for 24 hours on the 20th day after the mites infecting meal developed an infection averaging over 18 weekly counts, 97 mf./cmm. of peripheral blood (range 40-190 mf./cmm.) A third rat exposed to 3-13 mites of this series on the 25th day of their infection contained only one male *L. carinii*.

Cotton rats were found to be positive for the microfilariae of *L. carinii* in the peripheral blood-stream 51-54 days after a 24-hour period of exposure to infection by infected mites.

Non-infective forms of the worm with sickle-shaped tails occur on the ninth and tenth days of the worm's development, and the infective forms appear to be the active thread-like worms varying between 0.5 mm. and 1 mm. in length found from the 14th day to the 36th day after the mites infecting meal.

The percentage infection-rates in two series of mites dissected before the first infective meal were as follows: 38 per cent. of 29 mites were positive for 1-5 worms after engorgement on a cotton rat showing 2,584 mf./cmm. of peripheral blood. 21.8 per cent. of 39 mites were positive for 1-2 worms after engorgement on the same rat on a separate occasion when the blood count was 3,000 mf./cmm. of peripheral blood.

HAEMATOLOGY

BICHSEL, G. Hämoglobinstandardlösung zur Eichung von Häuometern nach Sahli und Zelenko [Haemoglobin Standard Solution for the Sahli and Zelenko Haemoglobinometers.] *Schweiz. med. Woch.* 1947 Dec. 13, v 77 No. 50 1312-13, 1 diagram. [12 refs.]

SCHERRERS G. W. H. Macrocytic Hyperchromic Anaemia on the Witwatersrand. Parts I & II. *South African Med. J.* 1947 Aug 9 & 23 v 21 Nos. 15 & 16, 566-75 603-11 9 figs. [13 refs.]

On the Witwatersrand, approximately 6,000 feet above sea-level, 300 patients with macrocytic or hyperchromic anaemia were discovered. As there was potential reservoir of approximately 50,000 persons the incidence of the anaemia was at least 0.6 per cent. which is considerably in excess of that for pernicious anaemia. A survey suggested that on the Witwatersrand, probably because of the altitude, 5.5 million erythrocytes per cmm. for men and 5 million for women, with corresponding increases in haemoglobin values, should be taken as minimum requirements. Observation showed that the haemoglobin concentration increases as the cell count, but that the rate of increase shows a diphasic, or perhaps tri-phasic trend. Thus for cell counts between 4 and 5 million per cmm. the rise in haemoglobin is very steep but above and below these limits the curve shows deceleration which is progressive as the lower and upper limits are approached. Similarly it was found that as the cell counts varied from 5 to 3 millions per cmm. the mean cell diameters increased from approximately 8.0 microns to about 10.0 microns, but beyond these limits in either direction the rate of change in cell volume was less than that of the cell count. A curve obtained by plotting the colour index against the mean erythrocyte surface showed no diphasic character the colour index increasing with increase of cell surface area up to the normal mean of 75 square microns per cell although beyond this the curve showed an increasing deceleration. In the macrocytic anaemias the concentration of haemoglobin per unit

VENOMS AND ANTIVENENES

GRASSET E. & CHRISTENSEN P. A. Enzyme-Purification of Polyvalent Antivenens against Southern and Equatorial African Colubrine and Viperine Venoms. *Trans. Roy Soc. Trop Med. & Hyg.* 1947 Oct. v 41 No. 2, 207-11

Enzyme-purification of polyvalent South African *Vaja ferox-Buth arideus* antivenene, and polyvalent *Buth gabonica* antivenene resulted in from four to six times concentration, and an increase in nitrogen content to approximately double the original amount. Group neutralising antibodies against other African colubrine venoms, namely *V melanoleuca* *V kaji* *N nigricollis* *Sepelex haemachates* and *Dendroaspis angusticeps* were concentrated to useful therapeutic levels. Limited protection was observed against the venom of *Buth marcoris*. The speed of union between enzyme-treated antivenens and venom is high.

The increased antibody concentration and purity of enzyme-treated antivenene marks a big therapeutic advance in the treatment of snake-bites, as compared with the antivenens previously prepared by fractional sodium sulphate precipitation, and its use reduces the risk of serum reactions.

DERMATOLOGY AND FUNGUS DISEASES

WILLIAMS, W. The Tropical Lichen Planus Syndrome. *Brit Med. J.* 1947 Dec. 8, 901-4 2 figs.

The author describes in detail three cases, and discusses a possible fourth case of this condition, the incidence of which was estimated at 1/2,000 troops. All were members of a New Zealand force operating in the Solomon Islands, a highly malarious region where suppressive mepacrine was administered to all troops at a rate 101 gm daily for six days in each week.

The patients two white soldiers and a quarter-caste Maori, had been taking suppressive mepacrine for eight to twelve weeks before the first symptoms developed and in all cases it was noted that fresh lesions appeared while mepacrine was being taken but ceased soon after its discontinuance.

The disease began as a patchy hyperkeratosis of the palms and soles, accompanied by thickening of the finger and toe nails which became brittle and opaque. Later a rash developed on the trunk and limbs which consisted in two cases of pink macules p to $\frac{1}{2}$ inch in diameter and in the third of raised bluish purple areas some of which were an inch in diameter. In two cases, lesions suggestive of syphilitic mucous patches developed on the buccal mucosa.

As the disease progressed scaling occurred on the individual lesions and variable degree of follicular hyperkeratosis developed on the back and shoulders.

The disease took a course of six to twelve months during which the thickened skin of the palms and soles was shed, and pigmentation occurred on the original patches. In some areas, vitiligo replaced the original pigmentation, and this variegated pattern appeared to be permanent. There was marked atrophy of the skin at the site of some of the healed lesions. Throughout the course of the disease the general health remained good. No evidence of spirochaetal or mycotic infection was found in any case nor was the author able to transmit the disease by inoculation of a volunteer with serum from scarified lesions.

The cases were therefore regarded as examples of tropical lichen planus, a condition which appears to be related to the use of mepacrine as a malaria suppressive

KULOWSKI, J & STOVALL S **Maduramycosis of Tibia in a Native American** *J Amer Med Ass* 1947 Oct 18 v 135, No 7, 429-32, 3 figs [Refs in footnotes]

CALERO, C **Cromoblastomycosis Acción *in vitro* de las sulfas sobre tres razas fungosas encontradas en el Istmo de Panama [Action *in vitro* of Sulphonamides on Three Strains of *Fonsecaea pedrosoi* in the Isthmus of Panama]** *Rev Inst Salubridad y Enfermedades Trop Mexico* 1947, June, v 8, No 2, 119-23

The English summary appended to the paper is as follows —

"In accordance with our observations 'in vitro,' in regard to the effects of four sulphonamides on the growth of three Panamanian strains of *Fonsecaea pedrosoi*, the sulphapyridine seems to produce the most notable inhibitory effects

"Our observations also seem to indicate that these drugs have a certain inhibitory effect on the sporulation of fungi studied, the effect particularly notable on phialophoric type of sporulation less effective on acrotheca sporulation, and much less notable on hormodendrum type of sporulation

"The study 'in vitro' on the four kinds of sulphonamides used in the growth of the three pathogenic strains of *Fonsecaea pedrosoi* (Brumpt) Negroni, 1936, encountered on the Isthmus of Panama, ratifies the observation 'in vitro' already reported by Pardo Castelló *et al* (1942)"

FORBUS, W D & BESTEBREURTJE, Annie M **Coccidioidomycosis a Study of 95 Cases of the Disseminated Type with special reference to the Pathogenesis of the Disease** *Milit Surgeon* 1946, Nov, v 99, No 5, 653-719, 37 figs (4 coloured) [236 refs]

This long and masterly description of the clinical and pathological features of coccidioidomycosis, which should be read in the original, is based on the study of materials obtained by biopsy and by necropsy from 95 cases of the disease in its disseminated form, supported by the clinical and pathological records

Following the method used in the classification of pulmonary tuberculosis, the authors distinguish two stages of coccidioidomycosis, (1) a primary complex which may be symptomatic or asymptomatic, and (2) an endogenous reinfection leading to disseminated disease. Hitherto, little was known of the pathology of the primary, pulmonary stage of coccidioidomycosis, in which death rarely occurs, but the authors "have been able to construct, according to well-established pathologic principles, the probable pulmonary reactions to the primary infection with *Coccidioides immitis*" and they recognize four forms of the pulmonary lesion (a) Lobular, focal, pulmonary consolidation strongly resembling the ordinary type of bacterial pneumonia, (b) extensive, gelatinous, focal or confluent, or lobular consolidation, (c) necrotizing, ulcerative bronchitis and bronchiolitis with bronchiectasis and bronchiectatic cavity formation, and (d) focal lobular or massive lobar, indurated, grey, moist, granulomatous consolidation. In its milder forms, the primary disease usually resolves without leaving any permanent change in the lung tissue, but the suppurative and the granulomatous, necrotizing lesions heal with scar formation. It is noteworthy that the authors found calcification of these lesions

this type of heat-exhaustion was due to local causes. Australian Army physicians described a similar syndrome in which, by means of serial sections of skin, they found blocking of the superficial parts of the sweat ducts and cystic dilatation of the ducts beneath the block. Polyuria was marked in this syndrome. Heat-exhaustion type 2 does not endanger life no case developed into heat-stroke. Yet it was of military importance, because the incidence was high and the rate of recovery slow.

ii. Work done by the Heat Physiology Team at the National Hospital, London, on the effects of high temperatures on man is described by Ladell. With acclimatization to heat sweating starts at a lower rectal temperature, and later reaches a higher rate for a given rectal temperature. At the same time the cardiovascular system becomes adjusted, probably because of an increase in the plasma-volume. Men are apparently physically efficient, and able to continue work for periods up to two hours, with rectal temperatures of 102°F., but in the light of observation and personal experience 101°F. was taken as the acceptable upper limit. The sweat glands appear to become fatigued rapidly at high rates of secretion. The decline of sweating after a certain length of time occurs whether the subject is replacing his water (and salt) losses or not.

The points considered in deciding whether the given environment should be regarded as tolerable or not were (i) whether one or more subjects in the group failed to stay the course for four hours (ii) a final rectal temperature (after work) above 101°F. (iii) an average sweat-rate over the whole period of more than 1,250 cc. per hour and a final (after work) pulse-rate of more than 140 per minute. By the use of these criteria, contour lines showing limiting environments were drawn. Of interest and importance is the notable effect of low air speeds. Thus, for men working in shorts, an increase in air speed of from 10 to 25 ft. per min. raised the wet bulb tolerance by 1°F. at high humidities and by 2°F. at low ones. It increased the dry-bulb tolerance by 5°F. and 10°F. at high and low humidities respectively. Increase of air movement from 75 to 200 ft. per min. increased the wet-bulb tolerance by only 1°F. and the dry bulb tolerance by 10°F. at all humidities.

iii. In a further paper Ladell describes an experimental study of the effects on man of restricted water-supply. The work was done on behalf of the Committee for the Care of Shipwrecked Personnel. When little or no water is taken there is a rapid fall in body-weight, because of the cumulative water debt contracted within the body. In a temperate climate a water intake of 800 to 900 cc. per day was needed to maintain water balance. Physical deterioration ran parallel with weight loss. A 5 per cent. loss was tolerable, but with 10 per cent. loss, such as occurred after 60 hours deprivation gross deterioration, physical and mental began to set in. Some constituents of lifeboat rations had diuretic effect and proposals were made for amended rations. Measures for increasing the water supply in lifeboats were explored. Diuresis is caused by the drinking of sea-water but with intakes of less than 400 cc. per day the increase in urine volume is less than the volume of sea-water drunk, so that there is a net gain of water to the body. Higher intakes of sea-water cause a drain on body water hence larger amounts of sea-water are dangerous. Water requirements are high in the tropics, and water deprivation very quickly causes dehydration. Thirst is a poor index of the need for water and it was recommended that each man should drink enough to produce at least beer-bottle and a half (about 850 cc.) of urine each day.

iv. The effects of a tropical climate on men in warships are discussed by Ellis. A Sub-committee of the Royal Naval Personnel Research Committee recommended that an effective temperature of 80°F. was the upper desirable limit for working and living compartments in ships, while 86°F. was the upper acceptable limit. The average thermal conditions in eleven ships with the

Tropical Ulcer

Vol 45, No 3]

Eastern Fleet in 1944 are tabulated. In each type of compartment listed, the average effective temperature exceeded the upper desirable limit, and in most of them the upper acceptable limit was exceeded. Sickness rates, and causes of sickness, in 28 ships and 6 naval shore establishments are discussed. Prickly heat was very prevalent, and affected 80 to 90 per cent of the men at one time or another. Excluding prickly heat, 9 per cent of the effects of heat on the efficiency of wireless operators, carried out by Mackworth, are summarized. Efficiency declined when the effective temperature was between 83° and 87.5°F, and at higher temperatures observed in wireless and radar offices that the average effective temperatures were about 86° and 87°F, respectively. v Weiner discusses the biological assessment of clothing for use in tropical service. For most military purposes, the thermal study of clothing is reduced to a few easily-measurable criteria—rectal temperature, pulse-rate, sweat output, water regain by clothing, and, where possible, the evaporated and un-evaporated fractions of the sweat-loss of the subject. It is important that subjects shall be fully acclimatized before clothing tests are begun. In examining fabrics for mosquito-proofness, main reliance was placed on a test in which an arm, covered with the fabric, was exposed to the bites of 200 starved *Aedes aegypti*. The number of weals in 15 minutes was noted. The physical characteristics of clothing fabrics relevant to performance in the tropics are the thickness, weight per unit area, water-vapour resistance ("ventility"), air permeability, water absorption and drying-out, and the construction of the cloth. Fabrics for special service garments were studied.

TROPICAL ULCER

STERNFELD, J & HIRSCH, W. *Ulcus Tropicum Clinical and Bacteriological Description of its Epidemic Occurrence in Haifa, 1944* Harefuah
Jerusalem 1947, Nov 16 v 33, No 10 [In Hebrew 157-62,
5 figs & 1 graph English summary 162]

In the first half of 1944, 7 cases of classical tropical ulcer occurred in Haifa among immigrants from the Yemen. In the summer, an epidemic of 122 cases occurred among the local Jewish population. The two forms differed: the ulcers of the Yemenites were typical chronic tropical ulcers of a severe form, and 5 of them showed spirochaetes as well as fusiform organisms. The epidemic ulcers were mild, without general symptoms, easily cured and spirochaetes were found in only 5 of the 122. (Nevertheless, spirochaetes were also absent from 2 of the 7 Yemenite cases.)

Although the presence of spirochaetes seems to increase the virulence of tropical ulcers, the authors believe that it is not necessary to their development. The characteristic microbiological finding is that of fusiform bacteria, with or without other organisms. Severity depends largely on the patients' general health and nutritional state, on clothing and on climate. Up to the present, tropical ulcer has been rare in Palestine and has occurred only in epidemics initiated, it is claimed, by the arrival of Yemenite immigrants, but it is not thought that, even if it became endemic in Palestine, it would acquire the severe character so commonly encountered in the tropics, so long as the conditions for its malignant development do not exist in the local population. [What those conditions are is not indicated in the summary apart from the general factors mentioned above, which are somewhat vague.]

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

ROCKEFELLER FOUNDATION INTERNATIONAL HEALTH DIVISION **Annual Report 1946** pp ix+239, 14 figs on 7 pls New York 49 West 49th Street

The report for 1946 maintains the same attractive format, and the same easy and interesting style, as its predecessors. The bulk of work done during the year relates to yellow fever in S America and Africa, malaria studies in relation to chemotherapy, and to control in many parts of the world, influenza and other respiratory diseases, rickettsial diseases, nutritional diseases, virus studies, and syphilis, diphtheria, tuberculosis and certain other subjects. There are also sections dealing with aid to state and local health services, health care, and public health education. At the end is a statement of expenditure each year since 1940, and for the period 1913-1939.

Most of the work published by the members of the staff of the International Health Division has been reviewed in the *Tropical Diseases Bulletin* or the *Bulletin of Hygiene*, but in the short compass of this report the reader will find interesting consecutive accounts of these researches, which will give him a clear idea of their scope.

BOOK REVIEWS

HEGH, E [Ingénieur Agronome, Lauréat de l'Institut de France, etc] **Les tsé-tsés Description—biologie—moyens de destruction** [Tsetse Flies their Morphology and Biology and the means of destroying them] 115 pp, 29 figs 1946 Brussels Ministère des Colonies Direction Générale de l'Agriculture et de l'Élevage, Place Royale, 7

This book is a useful introduction to the subject of tsetse flies in general and to those of the Belgian Congo in particular. It admirably suits the requirements of the newcomer to the subject, whether medically interested or not. Where advanced work is referred to in the text and the author lists some of his own publications at the end, otherwise there is no bibliography. There is no index of the ordinary sense, but the table of contents is so comprehensive that although the purpose of illustrations of tsetse anatomy and of breeding-places collected from well-known sources is obvious, the author has managed to get into so little space by explaining the importance of his subject and gives some notes on the biology of the study of *Glossina* and trypanosomiasis. From this, he describes how tsetse flies may be recognized and distinguished from other species. This leads on to descriptions of anatomy and to classification. Aspects of bionomics are touched on and their importance is dealt with, followed by descriptions of the larva and the biology of the fly, relation to game and domestic animals, such as seasonal movements of the fly, feeding habits. Notes are given on the characters of various species of *Glossina* as found in the Congo, other species are briefly mentioned. The book closes with accounts of some natural enemies, parasites and general factors mentioned.

The characteristic of the book is that it is written for the newcomer to the subject, without other organs of health and nutrition. It is a tropical ulcer book. It is thought that, even if it is a severe character, it is a book for its malignant conditions for its general factors mentioned.

predators of adult and pupa and with methods of control, including bush-clearing, eradication of game, systematic trapping and the treatment of cattle. Finally there are a few words about the future possibilities of DDT and Gammaxane in the control of *Glossina* when these are applied to animals in the open or in stables, or used in whitewash or in cattle dips.

In the appendices are keys for the identification of tsetse flies in groups of species and as separate species both as adults and as pupae. H. S. Lucas

GELFAND Michael [M.B. (Cape Town) M.R.C.P. Govt. Med. Officer Salisbury Native Hospital, Southern Rhodesia]. *African Medical Handbook. An Outline of Medicine and Hospital Practice for African Nurses, Orderlies and Medical Assistants.* 202 pp. 22 figs. 1947 Cape Town The African Bookman. [15s.]

The fact that another *adeo succum* for African subordinate medical staff has been produced is a welcome sign of the increasing recognition of the need for adequate training of this class of worker in the Colonies and in Southern Africa.

Unfortunately as the author points out in his preface, there is little uniformity in the designation, status, responsibility and functions of these men and women in the various dependencies. Inevitably therefore the length and type of training vary according to whether they are destined to serve as nurses, first-aid workers, orderlies, dressers, dispensers, public health inspectors or medical assistants.

It follows that there is a demand for a variety of text books with slightly differing approach and content. This one appears to be a combination of a nurse's manual and a general synopsis. It would appear to be more suited to the nursing orderly for one is constantly reminded that this or that condition or treatment is to be referred to the doctor. There is no section on clinical pathology nor on dispensing both of which would be needed by a worker in charge of a dispensary.

The matter is arranged in 14 chapters, under systematic heads including three topical chapters on Disorders of Nutrition, Tropical Diseases, and Infectious Diseases. The author encounters the usual difficulties in getting things to fit this scheme, e.g. yaws is dealt with under tropical diseases while tetanus is among the infectious diseases. Scabies is raised to the dignity of a tropical disease. A chapter on skin diseases would have been an advantage from many points of view. Salpingitis and ectopic pregnancy are shown under "The Alimentary Tract".

Diagrams are original but not too easy to follow as one must start reading life cycles from the bottom up if one is to work from the known to the unknown, the best tutorial method for backward folk.

Apart from these minor criticisms, the matter is well and clearly set forth in orthodox lines. There are few mistakes ("morbillus" for morbilli being one) and the printing is good. It is a pity that the price has to be 15s. for 200 pages, but the handbook will undoubtedly be popular among those to whom it is intended.

SUMMARY OF RECENT ABSTRACTS •

III. MALARIA

(Continued from p 228)

Treatment

A most comprehensive survey of antimalarial drugs has been edited by WISELOCKE (p 1106). It contains a record of the enormous number of compounds tested in the United States during the war. In a series of 6 papers, BRONIE and his colleagues (p 794) have given an account of the methods devised during the war for estimation of basic organic compounds in biological material in connexion with the evaluation of the large numbers of chemotherapeutic agents investigated.

A method of standardization of tests for antimalarial activity of drugs has been devised by GILKIN and SCHUCH (p 970). It is the "quinine equivalent" which is the ratio of the amount of the drug to that of the minimum effective dose of quinine as observed under well defined conditions in *P. cathemerium* infections of canaries.

SILVER (p 394) points out that strains of malaria parasites vary in virulence and in the amount of antimalarial drug necessary for treatment of the attacks they provoke and that much more of a drug is needed for a primary attack than for a relapse or reinfection.

RAYMOND (p 962) describes the Iotaquin prepared locally in Tanganyika territory during the war. PERRIER-GENTIL (p 396) writes favourably of a solution containing quinine gluconate and calcium for intravenous treatment of *P. vivax* infections. HERTZBLING (p 26) reports a case of quinine amaurosis in a patient taking therapeutic doses only. STRAGER and KEVIN (p 170) report a few cases of purpura in both *P. vivax* and *P. falciparum* malaria; this is a serious complication and is apparently an allergic reaction to quinine. No case was found in patients treated with atabrin.

KYKER *et al* (p 802) describe the formation of antimalarial agents by ultraviolet decomposition of quinine. In Holland tablets consisting of quinine and pain aquin are used in the treatment of *P. vivax* malaria to prevent relapse (WINKERL, p 696). Most *et al* (p 496) is a result of careful observation of a series of patients show that a combined quinine phisnoquine treatment is very much more efficient than

* The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947 v 14. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

SUMMARY OF RECENT ABSTRACTS *

III MALARIA

(Continued from p 228)

Treatment

A most comprehensive survey of antimalarial drugs has been edited by WISELOGLE (p 1106). It contains a record of the enormous number of compounds tested in the United States during the war. In a series of 6 papers, BRONF and his colleagues (p 793) have given an account of the methods devised during the war for estimation of basic organic compounds in biological material, in connexion with the evaluation of the large numbers of chemotherapeutic agents investigated.

A method of standardization of tests for antimalarial activity of drugs has been devised by GIVRICH and SCHUCH (p 970). It is the 'quinine equivalent' which is the ratio of the amount of the drug to that of the minimum effective dose of quinine, as observed under well-defined conditions in *P. cathemertum* infections of canaries.

SILVER (p 391) points out that strains of malaria parasites vary in virulence and in the amount of antimalarial drug necessary for treatment of the attacks they provoke and that much more of a drug is needed for a primary attack than for a relapse or reinfection.

RAYMOND (p 962) describes the Totaquina prepared locally in Tanganyika Territory during the war. FERRIT GENTIL (p 396) writes favourably of a solution containing quinine gluconate and calcium, for intravenous treatment of *P. vivax* infections. HERTZBERG (p 26) reports a case of quinine amaurosis in a patient taking therapeutic doses only. SHRAGER and KEVIN (p 170) report a few cases of purpura in both *P. vivax* and *P. falciparum* malaria, this is a serious complication, and is apparently an allergic reaction to quinine. No case was found in patients treated with atabrin.

KYKER *et al.* (p 802) describe the formation of antimalarial agents by ultra-violet decomposition of quinine.

In Holland tablets consisting of quinine and pamaquin are used in the treatment of *P. vivax* malaria to prevent relapse (WINCKEL, p 696). MOST *et al.* (p 486) as a result of careful observation of a series of patients show that a combined quinine-plasmaquine treatment is very much more efficient than

* The first list of references with this series of summaries has been compiled is given in the introduction which appeared in the *Tropical Diseases Bulletin* 1947 v. 44. References to all abstracts are given under the names of the authors placed on the pages on which the abstracts are printed.

McCALL (p. 366) show that sulphadiazine, given for fever with signs of pulmonary disease, delayed the true diagnosis of *P. vivax* infection by eliminating the parasites from the blood, for a time.

TRUFF (p. 485) advocates administration of nicotinic acid, in addition to anti-malarial drugs, in the treatment of severe *P. falciparum* infections basing this treatment on a consideration of the pathology of the disease and the action of the drug.

Suppressive Treatment

MARGRAITH *et al.* (p. 28) show that mepacrine in whole blood is largely concentrated in the white cell layer but they do not know if it is in the white cells themselves or in the platelets. The red cells and the plasma contain relatively little and the plasma concentration is better than whole-blood concentration, as an index of the red cell concentration. They (p. 31) give details of distribution of mepacrine in the tissues of experimental animals, and in various human secretions and tissues. Details should be sought in the original.

MARGRAITH *et al.* (p. 27) show that a prolonged trial of daily administration of mepacrine to 109 young women volunteers was followed in only one case by serious disorder and even that which was a psychosis, was not certainly due to the mepacrine.

FAIRLEY (p 398) shows that although in one area of New Guinea the failure of mepacrine suppression was largely due to faulty discipline, there was also a local, relatively mepacrine-resistant, strain of *P. falciparum* for which a double dosage was not too much. This strain was responsible for one-third of the overt attacks of *P. falciparum* malaria. Referring to this paper, SFRUM (p 398) states that discipline was no worse in the area concerned than in other areas, and that in that place it was never possible to arrange DDT spray, as was done elsewhere. He contends that there were many factors involved, and that variations in discipline may not have influenced the matter. FAIRLEY *et al* (p 399) investigated the mepacrine-resistant strains of *P. falciparum* referred to above, by inoculating them into volunteers. Even 0.2 gm mepacrine daily was not always effective in suppression, but paludrine in doses of 0.025 to 0.1 gm daily was a complete causal prophylactic. No evidence of mepacrine-resistant *P. vivax* was obtained. MACKERRAS (p 874) refers to this resistant strain of *P. falciparum* in Wewak, and remarks that similar resistance did not occur elsewhere, although for several months the troops were receiving inadequate amounts of mepacrine.

BANG *et al* (p 503) found malaria parasites in 14 per cent of a group of men under rigid mepacrine suppressive treatment, in which there had been only a few attacks of malaria, in a comparable group in which there had been much malaria previously, parasites were found in only 2 of 349. In Burma, under conditions of strenuous combat, 98 per cent of the men were protected by 1.0 gm mepacrine each week. GOLDSMITH (p 502) reports successful suppression of malaria in labourers on an estate in Assam, who were given either one tablet of chloroquine once each week, or mepacrine each day. There were no cases of intolerance to chloroquine.

In *P. vivax* malaria (New Guinea infections) TRAGER *et al* (p 1036) found relapse rates of 61-76 per cent some 4-7 weeks after cessation of suppressive mepacrine in men whose acute attacks had been treated with mepacrine and other drugs. After treatment with quinine the relapse rate was 82 per cent. BANG and HAIRSTON (p 1038) show that in a body of troops in the S. Pacific, the gametocyte rate in the men and the infection rate in mosquitoes varied in direct relation and argue that mepacrine suppression prevents infection.

ROBIN and BROCHEV (p 643) report a great reduction in parasite rates and spleen rates in African children (in Dakar) to whom mepacrine and rhodopraequine were given in several courses during a period of 4 months. PARKOR *et al* (p 700) show that both mepacrine alone and mepacrine and pamaquin, given twice each week to the inhabitants of part of Algeria, were effective in prevention of attacks of malaria. The gametocidal action of pamaquin, however, was not considered enough to justify its inclusion.

FINDLAY (p 763) has reviewed a large amount of literature on the toxicity of mepacrine in man. Lichenoid dermatitis and other forms of dermatitis of mepacrine in man. Lichenoid dermatitis and eye changes are described and toxic psychoses haematopoietic lesions and eye changes are discussed. The reader should consult the review itself for details. WILSON (p 395) discusses lichenoid dermatitis in relation to mepacrine. He thinks that this is the principal but not necessarily the only cause of the condition. KIERLAND (p 499) describes 49 cases of the eruption resembling lichen planus due to mepacrine. This almost invariably occurred in the older men at risk. The most serious complication was aplastic anaemia which was always fatal. CUSTER (p 697) reports that aplastic anaemia was much more common in men in the S. Pacific who were taking mepacrine than in those in areas where this was not necessary. In the 57 cases studied there was no evident correlation with any other drug and in 25 of them the anaemia was preceded by the atypical

MCCALL (p. 396) show that sulphadiazine given for fever with signs of pulmonary disease, delayed the true diagnosis of *P. vivax* infection by eliminating the parasites from the blood, for a time.

TRUFF (p. 495) advocates administration of nicotinic acid, in addition to anti-malarial drugs, in the treatment of severe *P. falciparum* infections, basing this treatment on a consideration of the pathology of the disease and the action of the drug.

Suppressive Treatment

MARGRAITH *et al.* (p. 28) show that mepacrine in whole blood is largely concentrated in the white cell layer but they do not know if it is in the white cells themselves, or in the platelets. The red cells and the plasma contain relatively little and the plasma concentration is better than whole-blood concentration, as an index of the red cell concentration. They (p. 31) give details of distribution of mepacrine in the tissues of experimental animals, and in various human secretions and tissues. Details should be sought in the original.

MARGRAITH *et al.* (p. 27) show that a prolonged trial of daily administration of mepacrine to 109 young women volunteers was followed in only one case by serious disorder and even that which was a psychosis was not certainly due to the mepacrine.

MARGRAITH and his colleagues (p. 496) found no indication that absorption of mepacrine was impaired by continuous administration of suppressive doses. In volunteers the mean plasma concentrations were about 26-28 $\mu\text{gm.}$ per litre on a dose of 0.1 gm. each day but individual variations were considerable. These workers (pp. 468, 499) working with volunteers, found that when 0.1 gm. mepacrine was given daily severe exercise under hot, moist conditions did not effect minimum mepacrine levels in blood or plasma, and that the final levels were not affected by the quantity of food taken, or by large amounts of cellulose. Elimination of mepacrine by the bowel varies between individuals, and may be quite considerable but it does not depend on failure of absorption.

SMITH *et al.* (p. 177) show that with small daily doses of mepacrine it takes 4-5 weeks to reach constant plasma levels with higher doses the time is shorter. BICKER *et al.* (p. 177) found plasma concentrations of atabrine [mepacrine] of 21.3 to 26 microgm. per litre in men taking 0.1 gm. each day. [The authors refer to levels of 21.3 G/L to 26.0 G/L, but explain that this represents microgrammes per litre. This use of the letter G is likely to lead to confusion.] In the *Archives of Internal Medicine* (p. 28) there is a report from the United States forces on plasma mepacrine levels. On 0.6 gm. each week the level rises slowly for 3-6 weeks, and then remains constant at about 30 microgm. per litre for each 1 gm. taken during one week. Priming doses of 0.3 gm. daily for 6 days raise the level more quickly. There is considerable individual variation in different people, and there is a group with very low levels this group was important in the war since it was necessary to give doses which would prevent malaria even in this group. A hot humid climate does not affect mepacrine absorption and storage there is no correlation between colouring of the skin and plasma mepacrine levels.

LEVINE and ERLANGER (p. 395) failed to find any effect of mepacrine administration on the electrocardiogram. BROWN and RENWICK (p. 467) discuss mepacrine metabolism in recurring *P. vivax* malaria.

BANG *et al.* (p. 281) found that mepacrine in a dose of 0.1 gm. each day was effective in suppression for troops in the S. Pacific a plasma level of 30 microgrammes per litre is satisfactory. In a series of cases of malaria in men who should have been taking 0.1 gm. mepacrine each day BROWN and RENWICK (p. 395) found that the usual reason for the apparent failure of suppression was that the men had, in fact not taken it regularly.

WILSON and ROBERTSON (p 1039) report on the use of DDT spray from aircraft in suppression of breeding of *A. gambiae* and *A. funestus* in East Africa. At a rate of 32 mgm per square metre breeding was immediately reduced by 98 per cent, the radius of control against these species need not be extended, in similar conditions, more than $1\frac{1}{2}$ to 2 miles. The main application of this form of control (which is relatively costly) would be in inaccessible or very extensive areas, or where speed is necessary.

MACINNES (p 701) shows that larvicidal oils containing DDT have some lethal action on adult *A. gambiae* and *A. funestus* when the latter are kept in cages containing bowls of water covered with such oils.

For control of *A. melas* in the tidal marshes near Freetown, TREDRE (p 488) excluded tidal water from the belts of *Paspalum* grass and *Avicennia* mangrove, by embankments, drains and sluiceways with tidal flaps. He supplemented these measures by the use of larvicides, and by destruction of adults. For the control of *A. melas* in West Africa, THOMSON (p 795) thinks that bunding is probably the most effective method, but the siting and construction of the bund are affected by local conditions.

A. sundaci breeds, south of Calcutta, in association with floating algae or submerged aquatic vegetation, but is inhibited by dense shade such as that given by the water hyacinth *Eichornia speciosa*. IYENGAR (p 564) has eradicated the larvae from ponds and swamps by cultivating this plant, and thinks that shade may act by killing the algae on which the larvae feed.

In the islands of Guadalcanal and Guam, during the war, dense forest was sprayed with DDT from aircraft as a means of mosquito control. HURLBUT *et al* (p 881) found that doses of 0.4 and 0.2 lb DDT per acre (in cyclohexanone and mineral oil) reduced adult mosquitoes and larvae by 98 and 99 per cent respectively.

Although conditions in 1945 favoured the breeding of *A. quadrimaculatus* in the Tennessee Valley, the expected outbreak of malaria did not occur, probably, as WATSON *et al* (p 801) suppose, because there were so few gametocyte carriers, owing to malaria control in the past. JONES *et al* (p 504) show that the 'para-para' isomer of DDT is about six times as toxic as the 'ortho-para' isomer, to larvae of *A. quadrimaculatus*. BRESCIA (p 881) has used DDT aerosols for killing larvae of *A. quadrimaculatus*, a dose of 0.001 lb DDT per acre killed almost 100 per cent within 12 hours.

DDT, in doses of 15-30 gallons of 5 per cent oil solution, emulsion or suspension, ensured about 75 per cent reduction of flies and mosquitoes, for 46 days, in salt marsh or jungle vegetation in the United States. Benzene hexachloride also gave promise of good results (MADDEN *et al*, p 1042).

In a comparison of DDT in the form of dust, spray and mist (in oil), and of paris green MATHIS *et al* (p 644) show that the DDT mist was the most generally useful in control of anopheline larvae. FERGUSON *et al* (p 645) give detailed information on the production of the DDT-oil mist.

In the Tennessee Valley Authority reservoirs many plants create problems associated with breeding of *A. quadrimaculatus*. HALL and HESS (p 1042) have experimented with 2,4-dichlorophenoxyacetic acid for control of growth of these plants, using it as a dust or as a spray. Details of the strengths of mixtures and solutions, and of method of application are given, this substance will probably prove more efficient and economical than mechanical means in the control of terrestrial plants and of most stiff-stemmed annuals, but it may have a deleterious effect on cotton crops in the vicinity, if it reaches them.

DEONIER *et al* (p 289) discuss some 6,000 organic compounds tested for toxicity to fourth-instar larvae of *A. quadrimaculatus*.

lichen planus which has been associated with mepacrine. BAZEMORE *et al.* (p. 556) describe 314 cases of lichenoid dermatitis, and conclude that there is strong evidence that the condition is due to prolonged ingestion of mepacrine, but that the mechanism of action is not known. In susceptible persons mepacrine may produce acute erythema and oedema within a few days, with positive patch test or the lichenoid fixed eruption after 2-3 months ingestion. BUTLER (p. 792) discusses 247 patients in the S. Pacific, with atypical lichen planus; he is not convinced that mepacrine alone is the cause of the eruption, though it is most probably an aetiological agent. VISANT (p. 877) also has reviewed the dermatitis due to mepacrine.

A blue-grey pigmentation of the nail-beds due to mepacrine is described by LUTTERLOH and SMALLENBERGER (p. 177).

AGRESS (p. 33) reports 5 cases of severe hepatitis and exfoliative dermatitis, of which 3 were fatal, due to mepacrine, and describes in detail the reasons for deciding that the drug actually caused these conditions in patients sensitive to it. A patch test with mepacrine will detect sensitivity. In an extremely sensitive person a toxic reaction may occur from ingestion of as little as 0.1 gm. of mepacrine.

Control

MACDONALD (p. 182) has published a useful booklet on malaria and its control, written for planters and miners. This cannot be abstracted.

JAME (p. 178) shows that malaria increased in French North Africa during the war but that in 1944 there was an abrupt decline in incidence. Rainfall was deficient in that year and antimalarial measures of many kinds were renewed with materials from American sources which during the early part of the war had been lacking.

HOCKING (p. 1038) makes the point that as a measurement of the efficiency of control assessment of the number of cases of malaria is too slow and too unreliable. The results of hand-catching of mosquitoes are preferable, and a standard trap hut has been devised. Senior WHITE and RAO (p. 794) on the other hand, have confirmed the contention of Ribbands that the method of hand-catching fails to capture a very considerable proportion of mosquitoes in buildings; spraying with pyrethrum is much more effective for estimating the total mosquito population.

Larvicidal Methods

SERGEANT and SERGEANT (p. 36) write of the value of colmatage which consists in causing silt-laden waters to deposit their silt in ponds and marshes, as an antilarval measure.

CAMBOURNAC *et al.* (p. 181) write very favourably of DDT in alcoholic solution as a larvicide for *A. maculipennis atroparvus* in ricefields: the alcohol ensures diffusion of the preparation. In ricefields in Kenya neither intermittent irrigation nor larvivorous fish reduced the number of anophelines but an oil-drop over the inlet channel was of value. GRAINGER (p. 844) shows, moreover, that intermittent irrigation probably decreased the crop.

WILSON (p. 156) shows very high incidence rates of malaria in European servicemen in various parts of East Africa during the war reduced as time went on and as control measures became more effective. The vectors were *A. gambiae* and *A. funestus* and the author thinks that though anopheline control may be very effective in controlling malaria for the greater part of the year larval control may fail to check the high seasonal incidence caused by *A. gambiae* in the more intensely malarious parts of East Africa. H. (p. 36) found powdered Derris root (2 lb. per acre) and Gammaxane (4 oz. per acre) effective larvicides, and gives the formula of a satisfactory oil which, at 5 gallons per acre, kills all larvae of *A. gambiae*.

WILSON and ROBERTSON (p 1039) report on the use of DDT spray from aircraft in suppression of breeding of *A gambiae* and *A funestus* in East Africa. At a rate of 32 mgm per square metre breeding was immediately reduced by 98 per cent, the radius of control against these species need not be extended, in similar conditions, more than 1½ to 2 miles. The main application of this form of control (which is relatively costly) would be in inaccessible or very extensive areas, or where speed is necessary.

MACINNES (p 701) shows that larvicidal oils containing DDT have some lethal action on adult *A gambiae* and *A funestus* when the latter are kept in cages containing bowls of water covered with such oils.

For control of *A melas* in the tidal marshes near Freetown, TREDRE (p 488) excluded tidal water from the belts of *Paspalum* grass and *Avicennia* mangrove, by embankments, drains and sluiceways with tidal flaps. He supplemented these measures by the use of larvicides, and by destruction of adults. For the control of *A melas* in West Africa, THOMSON (p 795) thinks that bunding is probably the most effective method, but the siting and construction of the bund are affected by local conditions.

A sundaticus breeds, south of Calcutta, in association with floating algae or submerged aquatic vegetation, but is inhibited by dense shade such as that given by the water hyacinth *Eichornia speciosa*. IYENGAR (p 564) has eradicated the larvae from ponds and swamps by cultivating this plant, and thinks that shade may act by killing the algae on which the larvae feed.

In the islands of Guadalcanal and Guam, during the war, dense forest was sprayed with DDT from aircraft, as a means of mosquito control. HURLBUT *et al* (p 881) found that doses of 0.4 and 0.2 lb DDT per acre (in cyclohexanone and mineral oil) reduced adult mosquitoes and larvae by 98 and 99 per cent respectively.

Although conditions in 1945 favoured the breeding of *A quadrimaculatus* in the Tennessee Valley, the expected outbreak of malaria did not occur, probably, as WATSON *et al* (p 801) suppose, because there were so few gametocyte carriers, owing to malaria control in the past. JONES *et al* (p 504) show that the *para-para*' isomer of DDT is about six times as toxic as the *ortho-para*' isomer, to larvae of *A quadrimaculatus*. BRESCIA (p 881) has used DDT aerosols for killing larvae of *A quadrimaculatus*, a dose of 0.001 lb DDT per acre killed almost 100 per cent within 12 hours.

DDT, in doses of 15-30 gallons of 5 per cent oil solution, emulsion or suspension, ensured about 75 per cent reduction of flies and mosquitoes, for 46 days, in salt marsh or jungle vegetation in the United States. Benzene hexachloride also gave promise of good results (MADDEN *et al*, p 1042).

In a comparison of DDT in the form of dust, spray and mist (in oil), and of paris green, MATHIS *et al* (p 644) show that the DDT mist was the most generally useful in control of anopheline larvae. FERGUSON *et al* (p 645) give detailed information on the production of the DDT-oil mist.

In the Tennessee Valley Authority reservoirs, many plants create problems associated with breeding of *A quadrimaculatus*. HALL and HESS (p 1042) have experimented with 2,4-dichlorophenoxyacetic acid for control of growth of these plants, using it as a dust or as a spray. Details of the strengths of mixtures and solutions, and of method of application are given; this substance will probably prove more efficient and economical than mechanical means in the control of terrestrial plants and of most stiff-stemmed annuals, but it may have a deleterious effect on cotton crops in the vicinity, if it reaches them.

DEONIER *et al* (p 289) discuss some 6,000 organic compounds tested for toxicity to fourth instar larvae of *A quadrimaculatus*.

WESTPHAL and HORTON (p. 565) have successfully used tricalcium arsenite in place of paris green (but in twice the amount) in control of breeding of *A. pseudopunctipennis* in Peru.

Spray-killing of Adult Mosquitoes

UPHOLT (p. 645) discusses the inactivation of DDT in nature, especially its adsorption on mud. HADAWAY and BARLOW (p. 1036) find that only 6-15 per cent. of DDT (in oil) remains on the surface of mud bricks, the rest being adsorbed—a better result (62 per cent.) is obtained from treatment with a water suspension of dispersible powder.

GORDON (p. 801) did not observe ill effects in men engaged for several months in preparing solutions of DDT in kerosene, and applying them.

RISBRANDS (p. 180) remarks that discovery of an efficient insecticide possessing no residual repellent or masking effect would be a considerable contribution to modern technique and shows that pyrethrum has a repellent action which lasts for at least 4 days. Lethane gives quicker knock-down than pyrethrum, and is less repellent but is more unpleasant. From careful experimental work, KIMMIDY (p. 581) shows that DDT irritates mosquitoes, causing them to leave a treated surface more quickly than a non-treated surface, though not causing them to avoid the treated surface. In this sense it is a repellent and the dose the mosquitoes receive may be irritant but not fatal. The work was done with *Aedes aegypti* and *Anopheles maculipennis atroparvus*.

SWILLENGREBEL (p. 285) discusses malaria in Holland, pointing out that wartime destruction of a large number of domestic animals may force *A. maculipennis meuseus* to feed more on man, and therefore perhaps to become a more efficient vector. The most important vector is *A. m. atroparvus*. Spraying of houses with DDT may be a useful measure of control. Experience with pyrethrum spraying during 10 years was satisfactory even in the epidemic year of 1944 (SWILLENGREBEL and KRAAN p. 286).

In a flooded area near the mouth of the Volturno River in Italy, ARICCIA (p. 800) applied DDT in kerosene to all habitations, in January 1945. Thereafter it was found that the average anopheline density in human and animal houses was enormously reduced until autumn and was accompanied by great decrease in the numbers of larvae in the swamps. Spleen and parasite rates were reduced. Anophelines were relatively numerous near any untreated shelter and the author concludes that in such work all buildings should be sprayed. *A. maculipennis lebranchiae* and *A. sacharovi* were the predominant species. SOMER *et al.* (p. 877) refer to the work described by ARICCIA and report similar work carried out in the delta of the Tiber where *A. m. lebranchiae* was breeding extensively in the flooded areas. DDT was sprayed in every house or shelter capable of harbouring anophelines, in spring 1945. The number of adults caught until late autumn was very low compared with previous records. Any unsprayed shelter greatly affected the numbers in the neighbourhood. The incidence of malaria declined continuously from March to the end of the year.

KARTMAN and DA SILVA (p. 38) show that relatively short contact with a DDT film in a glass tube is lethal to *A. gambiae* but in comment BURRIDGE points out that all the DDT would be on the surface of the glass which is not the case with many other materials.

DR MENDONÇA and CRAGUEIRA (p. 965) show that *A. gambiae* continues to be found in aircraft arriving in Brazil from Africa. Inspection and fumigation of arriving aircraft are compulsory because of the danger of this and other pests.

WILSON (p. 179) notes that in partially closed buildings, for spray-killing mosquitoes, the direct hit is essential, and the average fat gun is not satisfactory. Against *A. gambiae* and *A. fuscipes* spraying is necessary every day in the evening. Pyrethrum is an essential constituent but some DDT should

be added THOMSON (p 795) has demonstrated the important fact that within a few days of treatment of houses, in Lagos, with DDT in kerosene, *A. gambiae* and *A. melas* enter the houses at night, feed, and leave without resting. There was no appreciable mortality within 48 hours in those that left in this way. Dramatic reduction in house catches after treatment with DDT is no proof that mosquitoes of these species are being killed. He discusses malaria in the Africans, and makes the point that it is not known to what extent malaria contributes to the ill-health of West African adults.

HOCKING (p 879) shows that residual spraying with DDT is effective against *A. gambiae* and *A. funestus* in that it does not interfere with normal entry into a building, but that the mortality in those that have been able to feed, and therefore tend to rest, is very high. He gives details of dosages, and information on the effect of the various surfaces to which DDT was applied. In relation to *A. gambiae* and *A. funestus* in the Gold Coast, EDDEY (p 879) has found that spraying houses with DDT in kerosene, in various doses, is effective in reducing the numbers found at subsequent examination when counts were made of mosquitoes killed by pyrethrum spray [but see THOMSON above]. He calculates that such treatment would be needed every 2½ months, and notes that this method is more effective than continued spraying with pyrethrum, as was practised previously. In preliminary experiments on house-spraying with DDT against *A. funestus*, VINCKE (p 286) found that it does not prevent them from feeding, and has no repellent effect. Pyrethrum appears to have some initial repellent action, which gradually diminishes.

Senior WHITE *et al* (p 37) have published a critical review of the results attained in India by the spray-killing of adult mosquitoes with pyrethrum preparations; this has been more successful against *A. culicifacies* (which remains indoors, after feeding, until digestion is nearly complete) than against *A. minimus*. For the *A. fluviatilis* group, spraying for 6 days each week is the most effective; these mosquitoes leave the houses when digestion is only half complete, and are therefore vulnerable for spray-killing for only one daylight period in the cycle. Pyrethrum acts as a repellent to mosquitoes entering rooms. On the other hand, VISWANATHAN *et al* (p 38) think that for *A. fluviatilis*, spraying for 2 consecutive days followed by an interval of 1 or 2 free days, is satisfactory if antilarval methods are not possible.

In an experiment on control of rural malaria in India VISWANATHAN and PARIKH (p 798) conclude that residual DDT spray can be used economically and effectively, that a combination of spray-killing and larvicidal methods is too expensive, and that pyrethrum spray-killing is also too expensive.

Senior WHITE and GHOSH (p 799) have found DDT residual spray more effective against *A. fluviatilis* than against *A. culicifacies*, probably because the normal resting places of the former are walls and other places likely to have been sprayed, rather than furniture.

In relation to *A. minimus* in Assam, RIBBANDS (p 1041) found that spraying of houses with emulsions of DDT was more effective than with solutions, and that relatively heavy doses are preferable to light doses in view of their long persistence. Treatment of walls only, or ceilings only, may be effective. If the reduction of anophelines reaches 90 per cent there is, almost certainly, complete control of malaria transmission, but a repellent effect may be present which may reduce the actual degree of malaria control. Gammaxane was also tested but on a smaller scale; its rôle is not yet established.

BRADLEY and FRITZ (p 180) show that residual spraying with DDT is very effective against *A. quadrimaculatus* greatly reducing the number found in houses for as long as 4 months, and also the number found to contain human blood.

FAY *et al* (p. 582) have tested the persistence of toxic effect of DDT when sprayed on certain surfaces under experimental conditions. *A. quadrimaculatus* was used in these tests. Residues from 100 mgm. per square foot were unreliable for lasting effectiveness. The same authors (p. 563) show how much this type of surface affects the residual toxicity. A dried mud surface is particularly bad, and grease and smoke deposits reduce the effectiveness of the DDT. TARTWELL and FISK (p. 583) show that in rooms sprayed with DDT the resting time of *A. quadrimaculatus* was very much shorter than in unsprayed rooms. They suggest that some unengorged mosquitoes may be sufficiently irritated by DDT to leave before feeding. As a result of tests of the effectiveness of DDT spraying of houses and barns as a measure of control of *A. quadrimaculatus* HESS and KREMER (p. 880) conclude that treatment of houses alone is inadequate, and that if all premises cannot be sprayed, it is better to treat barns in preference to houses, since this mosquito rests in barns during the daytime more frequently than in houses.

A comprehensive report from Panama on the effect of spraying houses with DDT on the density of *A. albimanus* and on the incidence of malaria, is given by TRAPIDO (p. 287). The anopheline density is dramatically reduced and remains relatively low for several weeks, and a considerable degree of control may be effected in this way but spraying 3 months before the period of great anopheline abundance is ineffective in preventing the normal increase. Figures are given which show the reduction effected in the incidence of malaria by this means. *A. albimanus* is a wild mosquito which seldom remains long in houses. Nevertheless STEPHENS and PRATT (p. 564) found that spraying of houses in Porto Rico with DDT twice in one year produced a significant reduction in the parasite rate of the inhabitants.

GIGLIOLI (pp. 181-504) has found that *A. larlei* is particularly vulnerable by DDT. Females rest on the walls of houses before and after feeding. In sprayed houses in British Guiana great reduction in specimens captured in dwellings was observed during 9-10 months after spraying, and there was a significant fall in spleen and parasite rates in the people.

GAHAN and PAYNE (p. 880) show that spraying of villages with DDT not only very greatly reduced the number of adult *A. pseudopunctipennis* for several months, but reduced also the number of larvae found breeding in the adjacent ricefields.

Malaria of Monkeys Birds etc.

GARNHAM (p. 882) describes his discovery of exoerythrocytic forms of *P. falciparum* in *Cercopithecus* monkeys in Kenya. These bodies were found in the livers of 15 of the monkeys, and the author gives his reasons for considering them to be exoerythrocytic forms of this parasite. [This is the first occasion on which such forms have been described in mammalian plasmodia.]

In the Report of the Scientific Advisory Board of the Indian Research Fund Association for 1946 (p. 966) there is an account of the attempt made in India to find exoerythrocytic forms of *P. cynomolgi* in monkeys. The attempt was not successful, but a lot of information was obtained on mosquito transmission, transmission by injection of sporozoites, and infectivity of blood and various organs at different stages after infection.

WOLFSON and WINTER (p. 585) describe the course of *P. cynomolgi* infection in rhesus monkeys. TALLAFERRO and TALLAFERRO (p. 935) describe the course of asexual reproduction in *P. cynomolgi*.

MAJUMDER and DAS GUPTA (p. 183) describe the blood picture of normal *Macacus rhesus*, and discuss the anaemia produced in them by *P. knowlesi*. MCKEE and his colleagues (p. 1043) have studied the chemistry and metabolism of monkey blood, both normal and infected with *P. knowlesi* and

describe apparatus in which cultures can be maintained *in vitro*. Subcultures have been made for 7 generations, the parasites remaining infective. These papers contain much detail, and the originals should be studied.

SHEN *et al* (p 1045) find that red cells containing *P. knowlesi* develop increased osmotic fragility and are destroyed by mechanical trauma more easily than normal cells. This may be the basis of the haemolytic anaemia of malaria.

McKEE and GEIMAN (p 649) report work which indicates that the plasma level of ascorbic acid in monkeys infected with *P. knowlesi* is lower than the normal, and also that in monkeys rendered deficient in this vitamin, induced infection is less acute than in normal controls, such monkeys appear able to acquire immunity and control the infections.

RICHARDSON *et al* (p 289) have investigated the course of *P. knowlesi* infection of monkeys after measured infections, and have assessed quantitatively the great superiority of sulphadiazine over quinine in treatment.

EKZEMPLARSKAYA (p 182) shows that monkeys infected with *P. mui* become immune to the same strain, but not to other strains of the same parasite. He also shows that the humoral factor in the defence mechanism is insignificant in comparison with the cellular factor.

PEEL and RODHAIN (p 967) describe the schizogony of *P. reichenowi* in a chimpanzee. RODHAIN and LASSMAN (p 184) discuss the cultivation of the malaria parasites of chimpanzees, by the method of Bass. RODHAIN (p 801) describes a new malaria parasite of the gibbon.

WOLFSON and CAKRTOVA (p 566) discuss the relationship between the number of parasites and infected red cells in bird and monkey malaria.

STAUBER and WALKER (pp 967, 1046) describe a method of preparing suspensions of avian malaria parasites almost entirely free of any trace of red cell substance.

SEELER and OTT (p 185) discuss the effect of deficiencies in vitamins and protein on avian malaria.

DEARBORN and MARSHALL (p 568) find that various species of avian malaria parasites differ in their response to different drugs, and that a single species, therefore, is not satisfactory for the purpose of selecting drugs for test. MARSHALL and DEARBORN (p 292) show that in avian malaria a single daily dose of a drug may give results worse than, equal to, or better than those obtained by continuous drug-diet administration, according to the drug used.

TREMBLEY (p 402) has shown that *Aedes atropalpus* is a potential vector of *P. gallinaceum*. HOVANITZ (p 566) shows that there is little variation in infectibility of individual *Aedes aegypti* with *P. gallinaceum*. CANTRELL and JORDAN (p 39) show that the maximum number of oocysts occurs in *Aedes aegypti* when these mosquitoes feed on chickens infected with *P. gallinaceum* the day before the peak of parasitaemia, they discuss the possible reasons for this.

GORDON and HILL (p 402) describe their technique for obtaining suspensions of infective sporozoites of *P. gallinaceum*, which are bacteriologically sterile, from the salivary glands of mosquitoes.

TERZIAN (p 969) shows that splenectomy during the latent period adversely affects chicks infected with *P. gallinaceum*, though not those with the milder *P. lophurae* infection. This indicates that the lymphoid-macrophage system is actively involved in these infections.

CEITHAML and EVANS (p 567) exposed red cells containing *P. gallinaceum* to X-ray, and then injected them into clean fowls. High doses of X-ray reduce the infectivity of the parasitized cells, partially or entirely, but injection of these cells confers some immunity, as tested by subsequent injection of infective blood.

TALIAFERRO and TALIAFERRO (p. 40) report that chickens infected with *P. gallinaceum* show strong immunity to the same species and to *P. lophurae* but that chickens infected with *P. lophurae* show only slight immunity to *P. gallinaceum*.

Downs (p. 1045) shows that single trophozoites (*P. gallinaceum*) injected into normal chicks, give rise to schizogamous gametogamous and exoerythrocytic cycles.

TOLLIS (p. 968) describes the distribution of exoerythrocytic forms of *P. gallinaceum* in chicks, after blood infection. HAAS *et al.* (p. 290) describe their methods in obtaining heavy exoerythrocytic infections of chicks with *P. gallinaceum* for details the original should be consulted.

BRACKETT *et al.* (p. 291) have shown that infections with *P. gallinaceum* in chickens taking a diet deficient in pantothenic acid are much less severe than in controls, and that pantothenic acid is necessary for the erythrocytic stages of this parasite. The exoerythrocytic forms probably find enough pantothenic acid in their particular habitat. Analogues of this substance have an anti-malarial action in blood-induced, but not in sporozoite-induced, infections, and this is antagonized by pantothenate.

ZUCKERMAN (p. 504) has studied infections of chick embryos with *P. gallinaceum* induced by implantation of embryos of brain containing exoerythrocytic and erythrocytic stages on to the chorio-allantoic membrane, and by intramuscular injection of blood containing erythrocytic forms. It seems that infection through the membrane is effected only by the exoerythrocytic forms. Parasites in embryonic spleen can be grown by a tissue-culture method, and by exposing such spleens, containing exoerythrocytic forms, to various drugs, and then making tissue cultures, the effects of the drugs can be estimated.

MEYER (p. 968) has cultivated the erythrocytic form of *P. gallinaceum* in tissue cultures of embryonic chicken brain.

TOMLIN (p. 184) tested a number of drugs against exoerythrocytic forms of *P. gallinaceum* in tissue culture for details the original should be consulted.

BRACKETT *et al.* (p. 40) describe the antimalarial effects of metachlorodine against *P. gallinaceum* and in human malaria. It can act as a causal prophylactic against *P. gallinaceum* and is effective against *P. cathemerium* (HUGHES and BRACKETT p. 41).

CARLSON *et al.* (p. 39) have found that extracts of various plants are not only effective bactericidal agents, but also are lethal to *P. gallinaceum*: *vitro*.

GINGRICH *et al.* (p. 803) obtained radical cure of *P. cathemerium* infections with a naphthoquinone derivative.

BALL (p. 1045) has attempted to cultivate the mid-gut of *Culex tarsalis* containing oocysts of *P. relictum*, but although the stomach remained alive for 10 days, the oocysts did not develop.

COULSTON and HUFF (p. 970) describe the morphology of pre-erythrocytic forms of *P. relictum*. HAWKING (p. 970) has grown exoerythrocytic forms of *P. relictum* in tissue culture.

TRAGER (p. 1046) used a complicated medium for the cultivation of *P. lophurae*. True multiplication of the parasite occurs, and physiological studies are therefore possible.

HUFF *et al.* (p. 1046) have studied pre-erythrocytic forms of *P. lophurae* in turkeys, ducks, chickens and guinea fowl. They conclude that it is no longer possible to measure susceptibility of the host solely by the degree of parasitaemia, since some parasites exhibit numerous pre-erythrocytic forms, but only a mild blood infection. They give four criteria by which the suitability of a host for a given parasite may be measured.

RIGDON and VARNADOE (p 505) show that *relatives have the same* oxygen chamber than in air, and they discuss the *consequences of* human malaria. ROSTORFER and MCGEE (p 567) *in a study of* oxygen saturation of ducks infected with *P. lophurae* *in the* satisfactorily be condensed further RIGDON and ROSTORFER (p 568) *have* shown that death of birds infected with *P. lophurae* is *caused by* the blood to carry sufficient oxygen to support life, at the time of death *it* may have only 20 per cent of the normal oxygen capacity. FLETCHER and RIGDON (p 42) observed neurological disturbances (ataxia etc.) in *cases* which had recovered from *P. lophurae* infections, and think that *these may* have been due to anoxia, the result of anaemia, aggravated by vasomotor instability RIGDON (p 884) shows that deficiency of vitamin A *does not* significantly affect this disease, and RIGDON and MARVIN (p 884) that insulin injections do not affect it SEELER and OTT (p 41) show that *P. lophurae* infection in chickens on low-protein diet runs a much more severe course than in those on high-protein diet, even if total serum protein is normal It is known that hypoproteinaemia interferes with antibody production.

Roos *et al* (p 403) have investigated the different effects of deficiency of various vitamins on *P. lophurae* infection of chickens and ducks

MARSHALL and DEARBORN (p 292) have shown that in ducks infected with *P. lophurae*, and treated with mepacrine, similar plasma concentrations produced in individual birds by different doses are not equally active against the infection Great variations were found in different birds given the same dose, and these are probably due to differences in distribution between plasma and tissues (including erythrocytes)

WOLFSON (p 568) shows that *P. elongatum* attacks immature erythrocytes of ducks, and is a very fatal infection in spite of relatively low rates of parasitaemia. *P. lophurae*, on the other hand, attacks mature red cells, produces severe parasitaemia, but not so severe anaemia.

MANWELL (p 43) describes certain malaria parasites of bats

THOMPSON (p 43) shows that the action of quinine on the malaria parasites of lizards is similar to its action on the plasmodia of various warm-blooded animals THOMPSON (p 569) has observed the effects of mepacrine on the lizard malaria parasite, *P. floridense*

Charles Wilcocks

RABIES

LEPINE, P & ATHANASIU P Contamination spontanée du lapin par le virus de la maladie de Bornu Spontaneous Infection of a Rabbit with Borna Disease, *Ann Inst Pasteur* 1947, Aug, 73 No 8, 827-8

His note records the fate of one of a batch of 8 rabbits which had been used to titrate rabies virus by inoculation of brain substance from a rabbit *infectiously* infected with rabies. The titres employed were not lethal to 7 of the rabbits; the eighth died but histological examination demonstrated beyond doubt that the animal exhibited the lesions not of rabies but of Borna disease. The latter disease could be reproduced experimentally in fresh rabbits. The cause and mode of the infection is discussed and it seems to be likely that it was due to the virus of the other rabbit known to have Borna disease, which had

LÉPINE, P & ATHANASIU, P Evolution des lesions histologiques et des anticorps rabiques aux cours de l'incubation de la rage des rues [Development of Histological Lesions and of Rabieidal Antibodies during the Incubation Period of Street Virus Rabies] *Ann Inst Pasteur* 1947, Aug, v 73, No 8, 824-7

The time when the first histological lesions appear during the incubation period of rabies is of much theoretical and practical importance. Could it be demonstrated that the first lesions in the brain occur before the saliva becomes virulent, it would be possible to exempt from treatment persons bitten by an animal showing no symptoms of rabies and dead before the expiration of its period of observation. Of theoretical interest would be the establishment of a relationship, should such exist, between the occurrence of cellular lesions and that of serum antibodies.

To settle these questions, the authors inoculated 14 rabbits by the intracerebral route with a street virus strain (Corsican strain I), of which the full development in the rabbit regularly exceeds 18 days and averages 20. From the 48th hour after inoculation, the authors killed one rabbit every second day then from the 16th to the 20th day one rabbit every day. The brain, the two Gasserian ganglia and 1.5 cm of the main trunk of the sciatic nerve were removed from each animal for histological examination, and parts were inoculated into mice for proof of the presence of virus. Moreover, before being killed the animal was bled and its serum titrated with suspensions of the same street virus strain to determine the existence of neutralizing antibodies.

From these experiments it emerged that, after the intracerebral inoculation of rabbits with the particular street virus strain employed, the first lesions in the brain appeared about the 4th day, while the brain became virulent only on the 8th day and death did not supervene until the 18th day at the earliest. The Gasserian ganglia showed lesions on the 8th day and gave evidence of virulence on the 10th. In the sciatic nerve, lesions were demonstrable on the 10th day, virulence was present on the 12th but, whereas virus remained in the brain up to the moment of death, there was observed in the Gasserian ganglia and in the sciatic nerve a diminution, indeed a total disappearance, of virulence from the 18th day.

Antibodies, which first made their appearance in the serum on the 10th day thereafter showed a regular increase up to the time of the animal's death, when a very high content was achieved.

JACOTOR, H Le gel d'alumine comme adjuvant du vaccin antirabique formolé [Alumina Gel as Adjuvant to Formolized Antirabic Vaccine] *Ann Inst Pasteur* 1947, Oct, v 73, No 10, 1028-30

The author had previously placed on record the 10-to-25-fold increase in immunizing power conferred by the addition of aluminium hydroxide to anti-cattle-plague vaccines made from formolized organic pulp. A similar procedure permits a reinforcement of the formolized antirabic vaccine in current use in many countries for prophylaxis against canine rabies.

The technique of preparation is briefly as follows: dogs are inoculated with fixed virus rabies by the intracranial route when they are completely paralysed, they are killed and their brains extracted. The infected brains after being finely ground in a mortar are emulsified with a little formolized water, after filtration through gauze the emulsion is placed in an incubator for 24 hours at 37°C, thereafter it is kept for 4 days at the temperature of the environment (25°-30°C). The emulsion is then divided equally, to one part is added an amount of alumina gel equal to or somewhat less than the mass of nervous

matter finally sufficient water is added to ensure a resulting dilution of 1 : 8. The remaining half is brought to the same volume with plain water and serves as the control vaccine.

Five sets of adequately controlled experiments were made, during which guineapigs in parallel series had been inoculated with a twice-repeated dosage, at three weeks intervals, of from 0.25 cc. to 2.0 cc. of either gel or non-gel vaccine—this had been kept at room temperature before use for periods ranging from 15 days to 7 months, at the end of which time a test dose of 0.02 gm. of street virus was administered in the masseters 3 to 5 weeks after completion of treatment.

It was found that vaccine, with gel added, protected 81 per cent. of the relevant guineapig series, while the control vaccine protected only 44 per cent. and that the test dose, which killed all the unvaccinated control animals, killed 3 times as many guineapigs protected by the ordinary formalized vaccine as those treated with gel-added vaccine. The author therefore concludes that the alumina gel clearly reinforces the protective power of anthracis vaccines prepared from formalized emulsions of brain pulp.

Finally it should be noted that in the case of the vaccine concerned, the action of the alumina gel is on a tissue pulp rendered wholly avirulent by the addition of formal.

GHODINI M. Dix années de traitement antirabique à l'Institut Pasteur de l'Iran (Téhéran) 1936-1945. [Ten Years of Anti-Rabies Treatment at the Pasteur Institute of Iran (Tehran) 1936-1945.] *Ann. Inst. Pasteur* 1947 Sept. v 73 No 9 900-902.

The author intimates that there was a change during 1936 in the method of anti-rabies treatment practised at Teheran from vaccination with dried cords to the use of 5 per cent. fixed virus rabbit brain in 1 per cent. phenolized water killed by exposure to 37°C. in the incubator for 24 hours.

The usual course of treatment is the daily administration subcutaneously in the abdomen of 6 cc. on 20 successive days, but in the case of severe wounding (multiple bites on the face) the daily injections are extended to 30 days.

No decentralization of treatment is possible.

During the 10 years of treatment with phenolized vaccine, there have been 38 deaths—most of these occurred at the beginning, middle or end of treatment some few one or two days after its completion. Of these deaths, 36 followed wolf bites, 1 was from dog bite and 1 from jackal bite. In all 38 cases there was considerable delay in reporting for treatment—a delay averaging 15 days from the time of biting (minimum 5 days, maximum 32 days).

During the 10 years under review no case of neuroparalytic accident was observed among the 2,135 bitten persons treated.

G. Stuart

REMLINGER, P & BAILLY J. La rage du loup: critérium de l'efficacité de la vaccination pasteurienne. [Rabies in the Wolf: Criterion of Efficacy in Pasteurian Treatment.] *Bull. Acad. Nat. Méd.* 1947 v 131 No. 30/31 597-9

The authors recall recent criticism regarding the efficacy of anti-rabies treatment by Pasteur's method. In their view definite proof of efficacy would be furnished by a statistical study of the results of treatment in cases of wolf bite. They point out that wolves are almost certainly rabid if they bite human beings and that the incubation period of rabies after bites by these animals is shorter than that for other animals. In the past there have been many instances of death in those actually under treatment.

The suggestion is made that in cases of severe wolf-bite the intensive method of treatment advocated by TERRAN should be adopted. The basis of this treatment rests on the assumption that the addition of bichloride of mercury to an emulsion of fixed virus gives a chemotactic effect to the inoculated material which results in the retention in the peripheral circulation of leucocytes, which otherwise might transport a quantity of virus by the blood stream to the central nervous system.

The authors further suggest increased doses at diminished intervals, compared with the dosage and interspacing followed in the classical treatment, they add that with killed virus vaccine the paralytic accidents previously encountered with massive dosage need not now be feared.

PUBLIC HEALTH REP. Wash. 1947, Aug 22, v 62, No 34, 1215-37 [30 refs] **Control of Rabies** Report by the Committee on Public Health Relations of the New York Academy of Medicine

The control of rabies in the United States has been studied and reported on by the Committee on Public Health Relations of the New York Academy of Medicine. Although the report under review is but an abridgement of the full Report, nevertheless the shorter version contains so much of value to those interested in rabies control that no abstract could hope to do justice to the many aspects of the problem treated. The reader is advised, therefore, to obtain and study the original document.

In the following review only the more important points receive consideration —

Between 1938 and 1945, the average annual incidence of reported rabies in animals in the U.S.A. was 8 775, with the last three years of the series above average. 1945 was the peak year. Notifications, however, are regarded as incomplete. Rabies occurred mainly among dogs, but many other animal species were affected. An epizootic among foxes has troubled the south-eastern States for some years.

One of the major difficulties in securing effective control over the disease is the lack of uniformity between States and counties within States of notification procedures and control measures. Thus in some States rabies in animals is not even notifiable and the laws regarding the licensing and vaccination of dogs follow no common pattern. A similar diversity exists in the laws regarding quarantine and the inter State movement of animals. This lack of legislative uniformity is reflected in the innumerable agencies charged with the enforcement of such control laws as exist. SCHOFER in the Yearbook of Agriculture for 1942 aptly sums up the existing situation. Rabies is an outstanding example of a dangerous disease which could be controlled or eventually

5 cc. of potent vaccine is recommended for dogs, when rabies has been reported in the area. Three injections administered at weekly intervals, are, however, regarded as producing a more certain immunity. This latter method was practised yearly by the U.S. Army during the Second World War and only one case of rabies developed among 19 050 dogs so immunized. In the case referred to it is possible that the routine vaccination had not been carried out.

The common line of control measures in the presence of established cases in various States has been—mass vaccination of dogs, free of charge to the owners—enforcement of quarantine laws—collection and disposal of stray dogs—and appropriate education of the general public.

The Report also includes a review of recent scientific developments, including the mouse inoculation test devised by WEBSTER & DAWSON in 1935 [this *Bulletin* 1935 v 32, 608]. This method is stated to give 10 per cent. of positive results in cases where Negri bodies had not previously been demonstrated. Stress is also laid upon the superior potency of vaccine irradiated with a new type of extreme ultra-violet lamp described by LARIVINSON *et al* in 1944 [*ibid* 1944 v 41 914], as compared with phenol or chloroform-treated vaccines or with vaccine irradiated by ordinary ultra-violet light. Protection by this special irradiated vaccine has been given against 20 000 M.L.D. compared with 2,477 M.L.D. for a control phenolized vaccine. Potency is said to be good after storage—no appreciable loss being detected after six months.

Reference is again made to the suggestion of HANSEL [*ibid.*, 1946, v 43 187] that the use of immune serum alone or in combination with vaccine given after a period of 6 days may effectively protect man against rabies.

Finally a series of recommendations by the Committee is submitted, urging the adoption of National control measures. The Federal agencies concerned, in co-operation with appropriate State agencies, should draw up a plan for the eradication of rabies. The inter State transportation of susceptible animals should be regulated and provision made for the control of animals entering the United States from foreign countries. Rabies should be made universally reportable. The annual licensing and vaccination of dogs is recommended with the suggestion that in urban areas the granting of licences should be contingent on vaccination. Three injections of 5 cc. of a potent vaccine at weekly intervals are recommended as constituting the method of choice, but a single shot injection of 5 cc. is of benefit when mass vaccination programmes are being carried out and triple inoculation is not practicable. Recommendations to promote control also include the quarantine and impounding of dogs during outbreaks. Educational campaigns should also be launched, giving publicity to the measures adopted.

IOJESCU D. Importanța vaccinării antirabice preventive și obligatorie în masa a câinilor în profilaxia turbarii. [The Importance of Mass Vaccination of Dogs in the Prevention of Rabies.] *Rev. Științ. Med.* Bucharest. 1946 May-Aug v 35 Nov. 5/8 424-30. French summary.

A wild strain of rabies virus obtained from a wolf was adapted to dogs by serial passage. At the present time the strain has undergone more than 300 passages, and the incubation period has become stabilized at 7 days. A phenolized vaccine has been prepared from the strain, and is considered to be more effective in immunizing dogs than one utilizing a strain of virus adapted to some other mammalian species. The use of the vaccine is devoid of risk, and it is suitable for the mass vaccination of dogs which is considered to be a rational and practical method for reducing the incidence of rabies. Experience of mass inoculation in other countries is briefly reviewed.

NOVICKY, R. Aportación al estudio de la rabia parolítica bovina en Venezuela [Bovine Paralytic Rabies in Venezuela.] *Bol Inst Invest Vet Caracas* 1946, Dec 3 No 13, 399-468 [35 refs.] English summary

MALARIA

DE MEILLON, B. The Anophellini of the Ethiopian Geographical Region. *Publications of South African Inst Med Res* 1947, Sept, v 10, No 49, 272 pp, 85 pls 1 map & 2 figs Johannesburg The Librarian South African Institute for Medical Research, Hospital Street [30s]

Students of African anophelines will welcome the appearance of this work as it brings together available knowledge and an up-to-date classification of these mosquitoes. The book is intended for those who already have some knowledge of the subject therefore there is no general account of mosquito morphology. Nearly a hundred species and varieties of *Anopheles* are dealt with, they occur in the continent of Africa south of the Sahara, the islands around it and a small portion of Arabia. Classification is based largely on the works of Root, Christophers, Edwards and Evans, with some modifications. Adult characters are used principally for the identification of subgenera and groups and larval characters for the identification of series. Subgroups have been abandoned in favour of series in order to maintain uniformity.

Phylogeny, zoogeography and the relationship of the species to malaria are briefly discussed, and breeding places are broadly classified. Keys are provided for the separation of subgenera, groups and series, there are also keys to females and to fourth stage larvae. The keys to pupae and to eggs are for the moment tentative as they will need revision as more precise information is accumulated.

The main bulk of the book (some 200 pages) is taken up with systematic descriptions of the species, though these are limited to the bare essentials. The chief distinguishing morphological features of most of the species are illustrated by numerous line drawings. Descriptions of pupae are not included in this section, as there is considerable doubt about the accuracy of some of the published descriptions. For each species there are notes on breeding places, relation to malaria and on distribution. At the end of the book there is a summary of the known geographical distribution of the species in tabular form, a valuable bibliography occupying eight pages and a most clearly arranged index.

The true value of a book of this nature can only be assessed after a period of use and reference, but there is no doubt that this publication is most timely. Both the morphological and the biological details have been most carefully assembled, and from the frequent notes which follow many of the descriptions, one gains the impression that the author has been to considerable pains to include ideas and results from the latest investigations. The general matter is of necessity somewhat condensed but in view of the extensive bibliography provided, not unreasonably so. For example, the important species *Anopheles gambiae* and *A. funestus* receive fourteen and eight pages respectively, but in each case only two pages are taken up with morphology, the remainder being devoted to biological matters. Other species of less medical importance are quite adequately dealt with in a page or two. Some species are of course not yet so thoroughly known, but as knowledge increases it becomes evident that previously accepted ideas about species relationships and species distribution must be modified. To take one point, cited by the author, *A. brunnipes*, a

species formerly known only from Angola and the Belgian Congo and recently shown to be a vector of malaria, is now recorded from Portuguese East Africa and the Rhodesias.

Modern methods of study including the rearing of species through all stages from the egg to the adult comparison of certain morphological characters such as the female pharyngeal armature, male terminalia and pupal paddles, have provided the worker with further clues to these relationships and have all combined to assist in the accurate identification of these important insects. For some time to come this book will be regarded as a major reference work on the subject of African anophelines.

SCHWITZ, J. Recherches sur les moustiques dans la bordure orientale du Congo Belge (Lac Kivu-Lac Albert). [Studies of Mosquitoes in the Eastern Border of the Belgian Congo.] Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales. Mémoires. (Collection In-8°) 1944 v 14 No. 1 93 pp. 8 maps (1 folding) & 9 figs. on 2 pls. [11 refs.]

The author collected 68 species of mosquitoes (15 Anophelines, 1 Megarthine and 52 Culicines) during a journey along the eastern border of the Belgian Congo between July and November 1939 this period covered part of the dry season and part of the wet season, and the country investigated ranged from south of Lake Kivu to the north of Lake Albert.

This publication contains annotated records of the collection arranged by localities, which are briefly described. There are sketch maps of some of the areas, as well as a map of the whole region showing the route followed. The substance of the paper is mainly entomological and is not easily summarized those interested would in any case have to consult it in the original. The collections are deposited partly in the Museum of the Belgian Congo at Tervueren, Belgium partly in the British Museum (Natural History) and partly in the Laboratory of Parasitology of the University of Brussels.

KALANDADZE L. P. & KAVILADZE O. P. [On the Blood-Sucking Mosquitoes of the Western Part of the Iran Azerbaijan.] Med. Parasit. & Parasitic Dis. Moscow 1947 v 16 No. 1 57-65 3 figs. [In Russian.]

With the view to filling the gap in our knowledge of the mosquito fauna of the Azerbaijan province of Iran the authors have made collections and observations in the course of two years, the results of which are described in this paper. Mosquitoes in this area are represented by the following forms: (1) *Anopheles maculipennis* is ubiquitous of the two subspecies present *A. m. maculipennis* is widely distributed, while *A. sacharovi* has a restricted distribution. This species is the most dangerous local vector of malaria. (2) *A. claviger* (*bifurcatus*) was found in Khoi and Maraga. (3) *A. algeriensis* which is a rare species, occurs in Maku. (4) *A. plumbeus* was seen once in Khoi. (5) *A. (Mynomyia) superpictus* is widespread, being second only to *A. maculipennis*. (6) *Theobaldia (Allothobaldia) longiareolata* is comparatively rare. It was encountered in Khoi, Maku and Sharif Khana. (7) *T. alaskensis* is rare, probably restricted to mountainous regions found in Maku. (8) *T. annulata* is the most common species of this genus, occurring in Khoi, Maku Shahpur Ruzach. (9) *T. annulata subochrea* was found only in Khoi. (10) *Aedes (Ochlerotatus) caspius caspius* occurs in Khoi, Shahpur Maku Beshkez and Tabriz. (11) *A. (O.) c. dornalis* is first recorded for Iran it occurs in Khoi, Shahpur Maku, Tabriz and Sharif Khana. (12) *A. (Aedimorphus) vexans* is found in Beshkez and Khoi. (13) *Culex (N. culex) deserticola*. One specimen only seen in Maku, but its identity

needs confirmation (14) *C (N) hortensis* a very rare species encountered in Karavan-Sarai and Maku (15) *C theileri* is fairly widespread, found in Khoi, Maraga, Maku and Karavan-Sarai (16) *C pipiens*, though known to be common, relatively few specimens were collected in Maku, Rizaeh, Ushna, and Maraga. Among the malaria vectors the most common and dangerous species are *Anopheles maculipennis maculipennis* and *A. superpictus*, while the most common culicines are *Aedes caspius*, *Culex theileri* and *C. pipiens*.

The authors further give some phenological data on the anophelines of Iranian Azerbaijan, viz, time of flight after hibernation, time of appearance of first aquatic stages, flight of first males and number of generations, preparation for hibernation. It is noted that all water collections play an important rôle in the distribution of the malaria vectors, but especially those which are connected with the irrigation system. Anopheline mosquitoes were encountered in dwellings of different types, including dug-outs and tents, as well as in barns and cellars, but they were especially numerous in animal-houses. Though the buildings do not provide the mosquitoes with shelter during the malarious season, they congregate there in large numbers for hibernation.

BEKLEMISCHEV, W N & SHIPITSINA, N K [*Anopheles marteri* in the North-Western Iran] *Med Parasit & Parasitic Dis* Moscow 1947, v 16, No 1, 66-7, 3 figs [In Russian].

The authors record the first finding of *Anopheles marteri* in the valley of the river Yuzbashchai of north-western Iran. It is noted that although the distribution of this species covers all the Mediterranean region from Spain and Algeria to Thrace and Syria, and extends to the mountains of Middle Asia, it has hitherto not been discovered between Syria and Tadjikistan. The present finding helps to fill the gap and leads one to expect to find this species in Southern Transcaucasia, including the mountains of Southern Azerbaijan [Iran] and Armenia. A description is given of the characters of the larvae of this mosquito.

WOODHILL, A R Observations on the Morphology and Biology of the Sub-species of *Anopheles punctulatus* Dönitz *Proc Linnæan Soc New South Wales* 1945, v 70, Pts 5/6, Nos 321/322, 276-87, 1 map and 3 figs

This paper is a further contribution to the discussion on the relationship and status of the forms of the Australasian anopheline mosquito occurring within the species *Anopheles punctulatus*.

The author holds that there are two subspecies (not species) *A. p. punctulatus* and *A. p. farauti* which may be differentiated morphologically by the palps in the adult and by the shoulder hairs in the larva. Certain other differences in larvae are not constant over the whole range of the species, but only in certain areas.

Besides these two subspecies, intermediate forms exist which the author believes to be hybrids and this idea is supported by evidence produced from field observations, for where one subspecies is present alone no intermediates have been recorded, whereas breeding experiments show that both adult and larval progeny of intermediate females exhibit all variations from the *A. p. punctulatus* to the *A. p. farauti* type.

It is essential that workers should attempt to cross one subspecies with the other on a large scale and demonstrate finally whether inter-fertility occurs.

With reference to *A. koliensis*, which appears to be constant in its characters in the Solomon Islands, specimens from New Guinea cannot be considered as

such, because they give rise to both *punctulatus* and *farauti* in their progeny, the author is therefore of the opinion that it is more logical to regard *hawaiiensis* as a subspecies of *punctulatus* than as a distinct species. H S Lesson

HARDMAN V F Studies on Imported Malaria. 3. Laboratory Rearing of Western Anophelines. J National Malaria Soc. 1947 Sept. v 8, No. 3 165-72.

This paper concerns the insectary rearing of *Anopheles maculipennis fressborni* in California and includes some notes on *A. m. occidentalis*, *A. punctipennis* and *A. pseudopunctipennis franciscanus*.

The insectary was a dull-white painted room of 1 050 cubic feet, provided with natural as well as fluorescent lighting. The temperature was about 28°C. and the relative humidity was between 80 and 85 per cent. Larvae were kept in shallow rectangular pans in water from the breeding place and only one batch of larvae was reared in the same water. The larval food was a mixture of 90 per cent. finely ground dog-food with 10 per cent. yeast. This mixture was dusted on to the water surface daily from the second or third day after the hatching of the eggs. Pupae were recovered daily and transferred to cartons, into which two or three large larvae were placed to consume the surface scum; this procedure reduced the previously very high mortality among emerging adults to about 4 per cent. All pipettes were rinsed in alcohol between moves, to prevent the contamination by bacterial scum being transmitted from one pan to another.

In seven months, 89,500 pupae were obtained and seven generations were passed through. The period from oviposition to pupation averaged 21 days over a range of 12 to 30 days at a water temperature of 27°C. Adults reared from larvae kept at 100 to 200 per square foot of water surface were smaller than field-collected adults, but those reared from larvae kept at 10 per square foot were about the same size.

Attempts to rear *A. m. occidentalis* and *A. punctipennis* have so far failed. A few attempts to obtain mating of *A. pseudopunctipennis franciscanus* were successful, but only in cages 14×14×36 inches or larger. It was found necessary to give blood-meals to females of *franciscanus* at least once before insemination occurred and no females were found inseminated until all traces of the blood meal were gone from the midgut. (In *A. m. fressborni* no relation could be found between blood-feeding of females and insemination.) Another point of interest mentioned is that both *boylii* and *franciscanus* types of eggs were produced from a single first generation, laboratory-reared, female *A. p. franciscanus*.

Four tables compare the rate of development of different generations of *fressborni*, the percentages of pupae obtained, the differences between field-collected and reared batches of mosquitoes and the hatchability of eggs of the various generations. H S Lesson

BATES, M. The Laboratory Colonization of *Anopheles darlingi*. J National Malaria Soc. 1947 Sept. v 8, No. 3 155-8.

When attempting to establish laboratory colonies of mosquitoes, techniques may have to be varied for different species, and though the author of this paper is not satisfied that he has discovered the most satisfactory methods of handling *Anopheles darlingi*, he gives an outline of his present procedure, because it has served to maintain the colony for three months in his laboratory in Colombia.

For the culture medium, experience showed that best results were achieved with stream water and surface loam, with bread crumbs as larval food. To induce females to feed and mate, no special lighting arrangements had to be made and it was found that as a source of blood a calf was more convenient and satisfactory than either man or the other animals tried. For egg-laying females, dark dishes were more attractive than white ones, and the most suitable cage size was 2 metres high by 1.5 metres square, or larger.

A. strodei and *A. argyritarsis* were also successfully reared under the same conditions as *A. darlingi*, but attempts to rear *A. rangeli* and *A. pessoai* failed.

GIGLIOLI, G. Laboratory Colony of *Anopheles darlingi*. J. National Malaria Soc. 1947, Sept, v 6, No 3, 159-64, 1 fig.

In British Guiana, after an attempt to establish a laboratory colony of *Anopheles darlingi* had failed at the sixth generation, a second attempt was made and resulted in a colony which has now flourished uninterruptedly for over two years, and which by December, 1946, had passed through 35 generations.

Three cylindrical netting cages (60 cm high and 35 cm in diameter) have been found to be sufficient and more satisfactory than the usual wood, wire and glass cages. White china finger-bowls and larger white enamel basins are used for the aquatic stages. It was soon found that the selection of water was extremely important, the best results being obtained from clean fresh water with a pH of 6 or 7, the local artesian well water was excellent. For the females, feeds of human blood were offered every morning between 8 and 10 o'clock, no animals were used at all. Larval food consisted of a proprietary poultry mash, either plain or mixed with yeast. As the laboratory is situated among irrigated fields of cane and rice (the natural habitat of *A. darlingi*), no special arrangement had to be made to create suitable climatic conditions indoors; the only precautions necessary were to see that the colony was protected from draughts and excessive light. A table gives the average monthly temperatures and relative humidities in the laboratory, a temperature of 80°F and a relative humidity of 85 per cent may be regarded as optimal. A second table summarizes the duration of the periods of development for each stage from egg to adult for different seasons throughout thirty generations. There are, of course, certain extreme deviations, but apart from these there is a general tendency for certain values to recur irrespective of season. First ovipositions occur usually 6 to 8 days after emergence, eggs hatch in two days, the larval stage lasts 6 to 16 days and the pupal stage two days. The complete cycle can be accomplished in from 10 to 14 days. [Regarding the rearing of *Aedes aegypti* see JOHNSON, below.]

ALBERTO ALVARADO, C. & HEREDIA, R. L. Observaciones sobre una nueva variedad del *Anopheles* (*A. pseudopunctipennis*) Theobald 1901, encontrada en la provincia de Tucuman (Nota previa) [A New Variety of *Anopheles pseudopunctipennis* in Tucuman]. In Inst. Med. Regional Tucuman Argentina. 1947 Nov. v 2, No 1, 73-8, 6 figs.

The English summary appended to the paper is as follows —

Using the morphological characteristics of the eggs as a basis the authors describe a new variety of *A. (A.) pseudopunctipennis* which they designate *p. personi*.

VILLALOBOS C. E. & VALDERRAMA DELGADO A. *El Anopheles punctimaculatus* en el Perú. [1 *punctimaculatus* in Perú.] 12 pp. Lima, Dir. gen. Salub. Serv. nac. antimalar. 1944 (Summary taken from *Rev. Applied Entom.* Sér. B. 1947 Dec. v 35 Pt. 12, 204.)

Although *Anopheles punctimaculatus* D. & L. had apparently not been recorded from Peru prior to 1942, it is now common in the district of Lima and is increasing. It constituted 80 per cent. of the Anophelinae taken in buildings in two localities in April-July 1944. Numerous breeding places occur in the coastal area, and in addition to the shaded and sometimes polluted water in which the larvae usually occur they have frequently been observed in still, clear sunny water together with those of *A. pseudopunctipennis* Theo. The importance of *A. punctimaculatus* as a vector of malaria has not been definitely established, but in the course of the authors' investigations, although dissection of about 1 000 females gave negative results, four of 135 taken in a house inhabited by two chronic malaria patients situated at a place some 13 miles from Lima, and two of 93 taken at a place 18 miles from Lima, showed sporozoites in the salivary glands. *A. pseudopunctipennis* is still considered to be the main vector however.

VON DRACHMANN J. Zur Frage der Wirkung des Hochgebirgsklimas beim Malariker. [On the Effect of Mountainous Climates on Malaria Patients.] *Acta Tropica*. Basle. 1947 v 4 No. 4 335-8.

The favourable effects of mountainous climates on malaria patients have not been satisfactorily explained says the author. By some it is ascribed to the general sense of well-being and consequent resistance to disease, by others to increase in red corpuscles and raising of the haemoglobin. Several other hypotheses have been put forward, such as changes in the fat and lipid ferments and vitamin A content of the serum. It is thought that a study of the reticulo-endothelial stage of the parasite may throw light on the subject.

On the other hand, malaria relapses are relatively common at mountain heights especially when there is a moist wind blowing. Further the endothelium is a tissue which readily responds to climatic changes and these reactions are rapidly set up when debilitated or sick persons reside at a height where moist south-west winds prevail.

The author suggests the following. The plasmodia under climatic influence do not enter the erythrocytes but remain, perhaps for months in the endothelium. At the same time the climate at high levels acting on the readily responding endothelium causes a flooding of the parasites into the blood-stream and so renders them more readily vulnerable to therapeutic measures. It is possible that in the endothelium especially the reticulo-endothelium at high levels, certain changes of a colloidal, histochemical, histophysiological or other nature might play a part in preventing penetration of the plasmodia into the corpuscles or in the development of endothelial forms. This solution of the question it is stated can at present only be suggested as research on it is completely wanting. [Not a very satisfying contribution and purely hypothetical.] B. Harold Scott

INVERNIZZI G. Osservazioni ematologiche mielografiche della malaria. [Haematology and the Myelogram in Malaria. *Rev. d. Malariologie* 1947 Oct. v 28 No. 5 234-47. (28 refs.)]

The English summary appended to the paper is as follows:—

* The author carried out haematological investigation on 230 malaria patients. The method of haemochromocytometric examinations and myelograms by sternal puncture was used and he reached the following conclusions:

" 1 In acute malaria the actual anaemia is not so severe as it appears from the clinical symptoms. The erythroblastic report [? findings] is scarce, and some myelocytes are found.

" 2 In chronic splenomegalic malarial infection leucopenia with monocytosis is observed. During the stage of acute infection, with shivers, a moderate leucocytosis (7,500-8,000) was seen, with neutrocytosis (70-80%) and a reduction in eosinophiles. As the temperature falls leucopenia returns (3,500-5,000) with neutropenia, mononucleosis and lymphocytosis. Mononucleosis and deviation of the Arneth count to the left are constant.

" 3 The parasitic report [? findings] of the bone-marrow was scarce in the myelograms and no erythrocytic forms were seen, but a strong erythroblastic activity was noted with inversion of the leuco-erythroblastic relation and increase of cellular mitosis. No megaloblastic transformation of the bone-marrow was observed, but increase of hytioid [? histioid] elements and a leucoblastic hyperactivity was noted."

VAN DER KUYP, E. De pols en ademhalingsfrequentie bij malaria. [The Pulse and Respiration Rates in Malaria] Reprinted from *Nederl Tijdschr v Geneesk* 1947, Mar 29, v 91, No 13, 735-9. English summary.

The author studied the relation between temperature, pulse and respiration in several patients suffering from the three main forms of malaria. 130 of them suffered from quartan infections, mostly of a chronic type.

Although the three factors sometimes corresponded sufficiently with the type of infection, the pulse and respiration curves appeared to be more sensitive indications than the temperature of the progress of the disease during treatment, since they became normal later than it, a prolongation of their abnormality is stated to have heralded relapses and even the initial attack could sometimes be anticipated by their variations. Hourly readings made these observations more pronounced.

It is suggested that as a result of "schizogony on a small scale," the amount of toxin released is too small to influence the temperature, but that the pulse and respiration are more sensitive to those toxins.

CALEY, F E de W. Clinical Impressions of Malaria and Liver Damage. [Correspondence] *Lancet* 1947, Dec 20, 926-7.

The paper by MAEGRAITH, ANDREWS and GALL [see this *Bulletin*, 1948, v 45, 234] reminds the author of cases of malaria with liver damage seen by him in Siam. He states that 400 men, being prisoners of war, were working on the Mergin road from May to August, 1945. Of these 100 died and half of them died in an unusual manner. The illness began with continuous fever of about 102°F. After 5 days, hiccup began and the patients became deeply jaundiced. After four more days, they became comatose, with stertorous breathing suggestive of hepatic failure and with hiccup after every few respirations. Three days later death occurred. Vomiting was present but was not severe, while complete anorexia occurred. There was no tendency to haematuria or general haemorrhage. The urine was scanty and coloured by bile pigment. There was some enlargement of the spleen and liver. Later, some of the patients were evacuated to Nakon Paton. The author heard that the blood slides showed *Plasmodium falciparum*. It is suggested that these cases were due to a hepatotoxic strain of this parasite. They did not resemble bilious remittent fever, which was not encountered. At another camp in Siam, there was a higher incidence of cerebral malaria than elsewhere. It seemed possible that the strain of *P. falciparum* was of an encephalopathic type. Blackwater fever

VILLALOBOS C. E. & VALDERRAMA DELGADO A. El *Anopheles punctimacula* en el Perú. [*A. punctimacula* in Peru.] 12 pp. Lima, Dir. gen. Salub., Serv. nac. antimalar. 1944 [Summary taken from *Rev. Applied Entom.* Sér. B. 1947 Dec., v 33 Pt. 12, 204.]

At another camp in Siam, there was a higher incidence of cerebral malaria than elsewhere. It seemed possible that the strain of *P. falciparum* was of an encephalopathic type. Blackwater fever

was sporadic in incidence—one in four of the patients died. Treatment was by intravenous mepacrine. Where dysentery occurred with malaria, it was the interaction of two diseases. \ cases of choleraic, algid, cardiac or purpuric type were seen. Three cases were seen which resembled acute haemolytic anaemia with air hunger and a lemon-yellow skin and conjunctivae, without haemoglobinuria.

C. M. Wenyon

HERVAREG C. A. Malaria Tertiana and Renal Injury *Acta Med Scandinavica*. 1947 Sept. 22, v 128 No. 6, 590-95. [12 refs.]

This paper contains a short account of four cases of malignant tertian malaria occurring in Finland, showing signs of renal disturbance. In three, the renal damage was of the character of focal nephritis. The kidney syndromes in all cases were relieved by antimalarial treatment. A short note is given of the literature on the subject of renal damage in malaria, especially damage to the tubular epithelium in malignant tertian evidenced by dilution of urine diminution in output and rise of blood non-protein nitrogen. The four cases referred to in the text are the only cases with renal symptoms in 1,500 cases reported over the years 1941-45.

B. G. Macgregor

BENHAMOU E. ALBOU A. ZERMATI M. & EISENBERG R. Hémorragie méningée au cours d'un paludisme à *Plasmodium vivax*. Considérations pathogéniques. [Haemorrhagic Meningitis during *Plasmodium vivax* Malaria.] *Algérie Méd.* 1947 Oct v 50 No. 8, 611-14

Haemorrhagic manifestations appear to be rare in malaria—the authors quote SHRAGER and KEAN [this *Bulletin* 1947 v 44 170] who met only 10 cases of purpura in 10 000 consecutive cases of malaria treated in Panama—none of the published cases noted by these authors included meningeal lesions.

The present case refers to an Algerian who complained of persistent headaches for five days accompanied by vertigo. Although he had a history of trauma on two occasions (one involving the neck seven years earlier) these accidents were not serious and could not be regarded as relevant to the present condition. For nine months, the patient had felt weak and experienced fever of a malarial type almost daily—he noticed a swelling of the abdomen and an intermittent discomfort in the left hypochondrium.

On examination, he looked thin with pale conjunctivae—the spleen was considerably enlarged, but painless. Lumbar puncture produced a reddish fluid, which did not coagulate on standing and which showed no micro-organisms on direct examination. Two blood films taken after an interval of 3 days, showed the presence of *Plasmodium vivax*. Haematological examinations revealed a normocytic, normochromic anaemia, with 2,300 000 red corpuscles per cmm. and 51 per cent. reticulocytes—cold agglutinins were present at a titre of 1/32.

The bleeding and coagulation times and the platelet count were as follows—

| | 1st day | 9th day | 29th day | 36th day |
|------------------|---------|---------|----------|----------|
| Bleeding time | 15 | 3' 30" | 3' | 4-45 |
| Coagulation time | 8" | 4 | 12" | 8" |
| Platelet count | 44 000 | 77 000 | 100 000 | 133 000 |

The haemorrhagic and meningeal syndromes both responded to quinine and the cerebrospinal fluid was normal on the 30th day

The authors refer to the literature of purpura in malaria [see this *Bulletin*, 1938, v 35, 728] and quote cases in which haemorrhages in different organs had been noted but none of these included the meninges, nor were they related to any one species of *Plasmodium* only

In Shrager and Kean's cases [and in that recently reported by MAMOU [this *Bulletin*, 1948, v 45, 237] the purpura followed on administration of quinine in 9 of the 10 cases in the present case, no such treatment had been given before the onset of the haemorrhagic condition

In discussing the pathogenesis of the condition, the authors quote BENHAMOU and NOUCHI (*C R Assoc française pour l'avancement des Sciences Algér* 1930, May), as having shown a significant decrease in platelets in malaria they also refer to a thesis, published in Algiers by ASSUS in 1945, which suggests that haemorrhagic manifestations are not uncommon in patients having a raised titre of cold agglutinins. The authors therefore conclude by posing the question: What complementary rôle may auto-agglutinins play in the appearance of haemorrhages during malaria? H J O'D Burke-Gaffney

WINCKEL, C W F Quinine and Congenital Injuries of Ear and Eye of the Foetus *J Trop Med & Hyg* 1948, Jan, v 51, No 1, 2-7, 3 maps [13 refs]

It is well known that temporary deafness or blindness may occur as a result of quinine intoxication

The author draws attention to 15 instances of congenital deafness and two of congenital blindness described in the literature as occurring in cases where the mother has taken quinine in pregnancy or just before labour. All these cases were noted in the United States of America, and the amount of quinine taken varied from quite small to large doses. In one instance, the mother had been given 90 grains daily, by mouth and injection, for 7 weeks during pregnancy, the child was deaf for 6 months after birth, but ultimately recovered and at the end of 17 months hearing was perfectly normal. [As the author remarks it is a wonder, if this statement is true, that the patient survived.] It was found that the auditory and visual defects were not influenced by the amount of quinine taken.

The cases described are very few, only 17 appearing in the literature and all from the United States, yet the world consumption of quinine is estimated at from 600,000 to 800,000 kilogrammes yearly. If quinine is an important cause of congenital deafness or visual defects, cases would surely have been met with and reported more frequently and from all malarious parts of the world. Further, there is no correlation between the endemic incidence of malaria in the various States and the proportion of their inhabitants who are deaf mute or blind. This is clearly shown in 3 maps which give (a) the endemic malarious areas in various States, (b) the ratio of deaf mutes, (c) the ratio of blind persons in various States.

It is of interest to note that several series of such congenital auditory and visual defects have been described in instances where the mother has suffered from rubella in pregnancy [see *Bulletin of Hygiene*, 1947, v 22, 172, 390].

[The reviewer has attended several hundred confinements in malarious districts among the non-indigenous population, most of whom had taken quinine at some time during pregnancy. In only one case was a case of deaf-mutism seen, the mother, a European, having taken 5 grains of quinine daily during almost the whole of pregnancy. The child subsequently turned out to be mentally defective and it is not thought that quinine can be blamed for the condition. It would be interesting to know whether a daily prophylactic dose of quinine taken over the course of years predisposes to deafness.]

PIOTR M. GOSK *aspects de la question des Totaguinas. (Some Aspects of the Totaguina Question.) Rev. Paludisme et Méd. Trop.* 1948, Jan. 15. No. 44. 1-17. [Refs. in footnotes.]

MACHELLA T. E., KIRKELMAN L. J. & LEWIS R. A. *The Intravenous Administration of Atabrine in Falciparum Malaria. Bull. U.S. Army, Med. Dept.* 1947 Dec. v. 7 No. 12, 1009-21.

Many authorities regard the intravenous use of atabrine (mepacrine) as dangerous. This paper is the result of observations on 125 Chinese soldiers treated in Burma during the active malaria season (June-October 1944) and a series of experiments was planned to learn how this drug could be given most safely by the intravenous route.

No attempt was made to select cases but those with severe cerebral symptoms received the larger doses. All cases in this series had positive blood films.

The degree of parasitaemia was graded as follows (1) rare to few (2) moderate (3) many (4) loaded.

The following schedules were used —

Intravenous atabrine 0.4 to 1 gm. of the dihydrochloride was dissolved in distilled water (0.2 gm. in 10 c.c.) and this solution was added to 1,000 cc. of normal saline and given by intravenous drip over a period of 3-4 hours.

Quinine the dihydrochloride (1.2 to 2 gm.) was dissolved in 30 to 50 cc. of distilled water and the solution was added to 1,000 cc. of normal saline and given by intravenous drip.

S.N. 6911 besulphate (a 4-amino quinoline derivative) 0.64 gm. was dissolved in 1,000 cc. of normal saline and given by intravenous drip.

Atabrine by mouth 0.2 gm. of the dihydrochloride was given every six hours for five doses and then 0.1 gm. thrice daily for six days.

Daily thick blood films were examined until two negative smears were obtained.

The results of treatment may be summarized as follows —

1. Atabrine by mouth (2.8 gm. in 7 days) 20 cases. The average duration of fever after beginning treatment was 45.6 hours. Blood films were negative on an average 3 days after beginning treatment. All cases responded to treatment and there were no toxic reactions.

2. Quinine (1.2 gm. intravenously) 10 cases. The average duration of fever was 45.6 hours in the cases where the attack was terminated by the single injection and blood films were negative after 3.2 days. No toxic reactions were experienced but in five patients the single injection failed to terminate the attack and additional antimalarial therapy had to be given. [The nature of the further treatment is not mentioned.] A single infusion of 2 gm. given to 3 patients produced alarming collapse and was discontinued.

3. Atabrine (0.4 gm. intravenously) 10 cases. The average duration of fever was 21.8 hours. Blood was negative after 2.3 days. No toxic reactions were observed, but in one case this treatment did not stop the attack.

4. Atabrine (0.8 gm. intravenously) 20 cases. Average duration of fever 29.1 hours, negative smear after 2.3 days. No toxic results followed and all cases responded.

5. Atabrine (0.8 gm. intravenously) 20 cases. Average duration of fever 24.2 hours, films negative after 2 days. All responded to treatment and there were no toxic reactions.

6. Atabrine (1.0 gm. intravenously) 25 cases. Average duration of fever 31.6 hours. Blood negative after 2.2 days. All cases responded, but in two instances mental symptoms of a temporary nature occurred, namely excitement, exhilaration and in one case a short generalized convulsion. Through an error the first of these patients had received his injection in 50 minutes.

7 S N 6911 (0.64 gm intravenously) 20 cases Average duration of fever 41 hours, blood negative in 25 days No toxic signs were noted and all reacted to the dose given

Eight of the 125 patients showed severe cerebral signs with coma, four of these being treated with 0.8 gm and four with 1.0 gm of atabrine intravenously, all with success No mention is made of the cerebral conditions in the remaining cases It may be noted that in half the cases so treated, a single infusion of intravenous quinine failed to control the attack Three cases of *P. vivax* infections were treated with 2.0 gm quinine intravenously, all three showing severe collapse shortly after the injection

Serum atabrine concentrations were determined by a field method [see this *Bulletin*, 1945, v 42, 443]

A factor which appeared to determine the serum atabrine level was the rate at which the injection was given, for a given dose a higher concentration was found when the injection was given rapidly The concentration tended to be highest at the end of the injection, varying from 200 to 540 microgrammes per litre except in one case where a concentration of 1,100 μ gm was found without detectable toxic symptoms After cessation of treatment the amount steadily decreased to an average of 20 μ gm per litre on the 5th day, although small amounts were found as late as the 3rd week

The authors conclude that —

1 Intravenous atabrine in dilute solution, i.e., in 1,000 cc of normal saline, is well tolerated, and amounts up to 1.0 gm can be given safely

2 The drug should be administered by the drip method over a period of 3 to 4 hours

3 Toxic manifestations are negligible where proper procedure is followed

There were no deaths in this series

The authors emphasize the fact that they do not suggest that the injection of this drug should be generally adopted as a routine method of treatment.

RAO A. R. G. A Case of Maniacal Excitement following Large Doses of Atebrin
Indian Med Gaz 1947 Aug v 82 No 8 479-80

MACKERRAS, M. J. & ERCOLE, Q. N. Observations on the Action of Paludrine on Malarial Parasites *Trans Roy Soc Trop Med & Hyg* 1947, Dec, v 41, No 3, 365-76, 1 coloured pl & 1 graph

The changes which the sexual and asexual forms of human malarial parasites undergo during the development cycle in man have been carefully observed in stained blood films of the untreated host and at various intervals after administration of paludrine. The development of the parasites in the mosquito has also been studied. Some of the observed facts have been briefly reported by FAIRLEY [this *Bulletin*, 1947, v 44, 282]. In the case of *P. vivax* it was found that the drug exerts its lethal action on the dividing nucleus of early schizonts and that growth occurs normally up to this point. Gametocytes are not visibly affected. Fertilization occurs in the mosquito stomach, but cysts fail to mature and the mosquito gut infection becomes sterilized. Gametocytes of *P. falciparum* likewise developed normally in blood, and reached the stage of encystment in the mosquito gut, but further development was inhibited and the infection in this case was also sterilized if a sufficient amount of drug had been present in the host blood. Gametocytes which survived some 12 days after treatment of the host was discontinued, developed normally in mosquitoes, traces of paludrine in the blood, sufficient at 10 days to affect development, had apparently disappeared by the 12th day. In the case of *P. malariae* the action

of the drug was on young schizonts but the parasite appeared to be more resistant than *P. vivax*. There is an excellent coloured plate depicting the changes brought about by paludrine on the asexual forms of the latter parasite.

JOHNSON C. G. & WALTON W. H. The Effect of Area Dosage, Solution Concentration and Drop Size of Sprayed Solutions and Emulsions of DDT against Mosquito Larvae. Bull. Entom. Res. 1947 Dec. v 38, Pt. 3 405-30 15 figs. & 4 pls.

This account describes war time experiments on a strip of mosquito-infested canal in Surrey about 1 100 yds. long and 40 ft. wide. The mosquitoes were mainly *Anopheles maculipennis* (successus) with a few *A. claviger*. The canal was a disused section with no water flow the centre carried patches of floating vegetation and the margins were fairly densely grown with reeds. Sections 20 ft. long and at least 40 ft. apart were chosen for the experimental areas. The applications were made by an ingenious machine which distributed the spray drops from a rapidly spinning disc this was moved backwards and forwards across the canal on a wire, thus treating the water in strips. The droplet size could be altered by varying the disc size and the rate of delivery was controlled by varying the liquid feed on to the centre of the disc. For uniform distribution, an eccentric disc with a spiral edge was most satisfactory. Estimation of results was made by regular dipping at intervals and at different distances from the bank all along one side of the canal. These dippings were made for several days before and for about a month after spraying.

The first experiment was made to determine the minimum lethal dose of DDT in an emulsion at 0.5 per cent. with droplets about 0.4 mm. diameter. The emulsion AMSO was made up from the following concentrate: 30 gm. pure DDT 400 ml. pool 3 oil, 200 ml. Amos A5A (an emulsifier mainly sodium oleate and cresol).

The second experiment was designed to compare DDT in oil (5 per cent. solution aided by solvent naphtha as an auxiliary solvent and oleic acid as a spreader) with the emulsion used in the first test.

The third experiment was to test the effects of droplet size.

The fourth experiment investigated the effects of dilution on oil solutions containing the same amounts of DDT per unit area.

Results —

1. The critical density of application appeared to be about 40 gm. DDT per acre (10 mgm. per sq. metre). Doses above this were not economically more efficient and doses below gave unreliable results, especially in water among reeds.

2. The oil solution gave results definitely superior to the emulsion, especially among the reeds at the edges of the canal.

3. The finer droplets tended to be blown away from the experimental plots and thereby these tests were handicapped. But where due allowance was made for this by estimating the quantities actually falling on the water there was no difference in efficiency between drops of 0.4 mm. diameter and of 1 mm. diameter.

4 Dilution of 4.3 per cent DDT in oil ten times (i.e., 0.43 per cent) gave almost the same, or slightly inferior, results where the actual quantity of DDT delivered to the water surface was kept constant

KUCHER, S S Testing Insecticidal Properties of the Preparation "Insectol" on Mosquitoes *Vrachebnoye delo* 1946, No 5, 245-6 [Summary taken from *Amer Rev Soviet Med* 1947, Dec-1948, Jan, v 5, No 1, p 70 Signed Otto HOKE]

"Insectol is a complex mixture of aromatic carbohydrates and sulphonaphtholic acids. The basic material for its production is the light medium coal tar oil, which is obtained as a by-product in rectification of coal tar. Mixed with water, in which it is highly soluble, it forms a milky emulsion. Its insecticide effect on *Anopheles maculipennis* was tested in laboratory experiments with 3, 4, 5, 10 and 20 per cent solutions. It was found that 40 cc of a 10 per cent emulsion, sprayed on one square meter of a floor or wall of a barn, killed 98 per cent of the mosquitoes within one hour. The same result was obtained with 20 cc of a 20 per cent emulsion. While these results applied to spraying in the open, the toxicity of insectol was found to be far higher when used in stalls and chicken pens. It was proved that insectol acted upon the mosquitoes by mere contact.

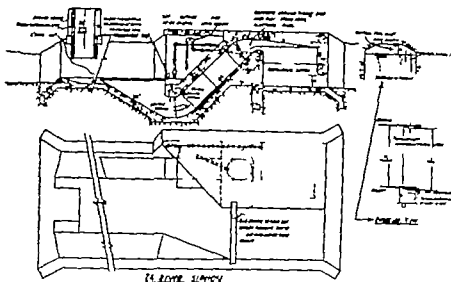

"For practical use 15 per cent emulsions are manufactured. The spraying of walls outside and inside buildings with 30 cc of this emulsion per square meter yields satisfactory results. For tightly closed rooms a 10 per cent emulsion suffices. The odor from spraying with the preparation evaporates after ventilation for five to six days. The unpleasant odor prohibits the use of insectol in human habitations."

PEREDO REYES E El cultivo del arroz y sus relaciones con el paludismo en el Estado de Morelos [Rice-growing and its relation to Malaria in the State of Morelos] *Rev Soc Mex Hist Nat* 1945 v 6 Nos 3/4 161-78 4 pls & 3 graphs

NEWBOLD, C E & COCHRANE, E Automatic Siphons for Antimalarial Control of Tropical Streams *J. National Malaria Soc* 1947, Sept, v 6, No 3, 192-205, 4 figs & 3 charts

Mechanical fluctuation and turbulence of streams in the wet season in the West Indies is believed to be responsible for the absence of the coastal anopheline, *Anopheles aquasalis*, which usually invades such streams in the dry season from the brackish coastal swamps.

A steady flow of water throughout the dry season permits the use of automatic siphons to produce the necessary flushing and turbulence. The authors consider that control of anopheline breeding is effected by damage to and stranding of eggs. Various types of siphons had been constructed previously without completely satisfactory control of breeding because of technical inefficiency of the automatic siphons. As a result of experience gained, a siphon (deep seal) of 24-inch diameter was built with simple but carefully designed automatic control devices. The best materials and workmanship were necessary to obtain a well-constructed supply reservoir with siphon in order to minimize maintenance costs, labour being expensive in Trinidad. For this particular siphon, a catchment area of 1 000 acres in the dry season enabled sufficient water to be impounded to produce an average discharge for ten minutes at the rate of 20 cubic feet per second, or about 70,000 gallons of water. The six-foot-wide stream was raised 17 inches at 2,000 feet, 13 inches at 6,000

Working design for 34-inch siphon for the control of mosquito breeding in tropical streams.

[Reproduced from the *Journal of the National Malaria Society*]

feet and $\frac{1}{4}$ inches at 10,650 feet downstream the wave took 80 minutes to reach the last point. Complete anopheline control was attained during six months observation. In comparison, RAMSAY in northern Bengal [this *Bulletin* 1941 v 38, 232] considered a total discharge of 50,000 gallons was the minimum amount necessary to control a mile channel (5,280 ft) 8 to 8 feet wide.

It is not possible to summarize the discussion and constructional detail given in this most useful paper but the appended working design will be helpful to those interested. To promote smoothness of action the authors have incorporated a 1 inch control siphon and an adjustable top to the control seal. Malaria engineers are strongly recommended to refer to the original paper with its clear diagrams and excellent photographs.

STAGE, H. H. & GIGLIOLI, G. Observations on Mosquito and Malaria Control in the Caribbean Area. Part II. British Guiana. *Mosquito News*, 1947 June v 7 No. 2, 73-6 2 figs.

The authors are of opinion that there are probably few countries where malaria constitutes a more serious problem than in British Guiana. In a population of 350,000 deaths ascribed to malaria are two per thousand inhabitants per annum—a much larger number of deaths due to anaemia, nephritis, prematurity and debility in infants are caused indirectly by repeated malaria infections—dangerous forms of the disease are frequent.

The inhabitants of the alluvial coastal zone, mixture of Negroes, Chinese, Portuguese and East Indians, accept malaria as inevitable. Filariasis is also a major problem and yellow fever a permanent potential danger.

The staple crops, rice and sugar cane, are dependent on extensive irrigation systems despite an annual rainfall of 80 inches. Much of the rice and cane fields along the coast are below high tide level and the practice of flooding fields, and the maze of irrigation channels provide most favourable conditions for

anopheline breeding There are fifteen anopheline species, mainly zoophilous, the principal exception being *A darlingi*, which bites man for preference and is found in houses in large numbers before and after biting

On the coastal zone, *A darlingi* breeds in large areas of fresh water such as canals and rice and cane fields In the interior, it prefers the clear water of ponds, lakes and streams Salinity and acidity of waters limit its distribution

A aquasalis and *A oswaldoi*, which breed in saline waters, do not appear to be efficient vectors of malaria

The ten years' observation by Giglioli indicate that sea defences, irrigation and associated cultivations, when used without discrimination between agricultural and residential lands, bring about the establishment of *A darlingi* and subsequently endemic malaria

Experience has shown that DDT applied as a residual insecticide is most effective against the vectors of malaria, yellow fever and filariasis, namely *A darlingi*, *Aedes aegypti* and *Culex fatigans* to the extent that they are "in grave danger of extermination" The cost is not excessive, amounting to slightly less than one dollar (British Guiana), per 1,000 square feet of surface treated

R Ford Tredre

GRAY, H F Mosquito Control Problems in Japan *Mosquito News* 1947, Mar, v 7, No 1, 7-11

Japan is infested with mosquitoes to the extent that people are so inured to insect attack as to be more or less indifferent to their presence

Ricefields produce the malaria vector, *Anopheles hyrcanus sinensis*, and the presumed and probable vector of Japanese B encephalitis *Culex tritaeniorhynchus* Cost prevents the use of larvicides, "intermittent drying in predetermined cycles" and the introduction of larvicidal fish are recommended to the government as effective and inexpensive control measures, where outbreaks of disease occur these measures may be supplemented by larvicides and residual insecticides

Water containers produce the vector of dengue, *Aedes albopictus* and *Aedes togoi* Epidemic dengue occurred between 1942 and 1944, an important contributory factor being *Aedes* breeding in the household concrete water-containers introduced for fire-control purposes Small containers in cemeteries are also notable breeding places

In the rural areas and unsewered portions of cities, human excrement is kept for fertilizer purposes in liquid manure tanks, *Culex pipiens pallens* and *Armigeres obturbans* breed profusely in these and other collections of foul water

Reasonable reduction in numbers of mosquitoes can be readily attained at very moderate expense *Anopheles hyrcanus sinensis* has a marked preference for large animals, and is effective as a malaria vector only if it is present in enormous numbers

Ignorance and indifference on the part of an impoverished population must be overcome by education before mosquito control measures can be effectively applied

[The co-author of the well-known text book on Mosquito Control methods has given a useful concise account of mosquito infestation in post-war Japan from the point of view of the military forces of occupation]

JOHNSON, H A Practical Laboratory Methods for Quantity Rearing and Handling of *Aedes aegypti* Mosquitoes to be infected with *Plasmodium gallinaceum* *J National Malaria Soc* 1947, Sept, v 6, No 3, 173-9, 4 figs

The methods of rearing *Aedes aegypti* described in this paper have been developed over a period of two years in connexion with studies of *Plasmodium gallinaceum* in chickens

The mosquito colonies are kept at about 75°F and at a relative humidity between 70 and 75 per cent. The cages are made of wire screening on 3-foot cubical frames with a front of glass having a 18-inch square opening fitted with a sleeve. A partially shaved rabbit provides the blood meal and 5 per cent. sugar water is kept in the cages. Eggs are laid on wet cellulose sponges these are removed every second day kept wet for 72 hours and then dried. The dried sponges may be stored for as long as two months to build up a reserve of eggs. After the sponges are immersed, hatching of the eggs is completed in 36 hours and the young larvae are removed to rearing pans and fed on ground Pabulum. Pupae develop in 6 to 10 days and the production is about 2,000 per day. Of these 800 female pupae are picked out for experiment and the remainder returned to the colony. The 800 pupae are placed in bowls (100 to a bowl) under lamp chimneys with bobbinet tops. 50 to 75 adults usually emerge from each 100 pupae in 1 to 3 days and the chimneys are then removed to the feeding room. Here they are clamped to platforms over one-inch holes which are closed with two thicknesses of rubber having cross slits through which the insects may be removed with a suction tube. Wet cotton is kept on the bobbinet for three days. Next day a chicken is placed across the bobbinet top and held by a cloth wrapping and rubber bands. about 50 to 90 per cent. of the mosquitoes feed in half an hour and the gorged females are removed to a fresh chimney on which is a cotton pledget soaked in 5 per cent sucrose. After 10 days, a few mosquitoes are examined for sporozoites and sporozoite inoculations are usually prepared from the 12th to the 15th day.

Unused females are kept until they die and some have lived for 110 days though usually only .5 to 30 per cent. survive after a month.

H S Lacey

HAAS V H & AKERS H. Transmission of *Plasmodium gallinaceum* by *Anopheles quadrimaculatus*. J National Malaria Soc. 1947 Dec. v 6 No. 4 244-5.

Plasmodium gallinaceum has been successfully transmitted by at least 27 species of mosquitoes (belonging to five genera—*Aedes*, *Armigeres*, *Culex*, *Mansonia* and *Theobaldia*).

These authors report success for the first time with the use of an anopheline mosquito *A. quadrimaculatus*. The mosquitoes were obtained from a long established colony and were allowed to bite chicks whose blood contained gametocytes of *P. gallinaceum*. The insects were kept at 74-76°F in a relative humidity of 70 per cent. After 10 days, three stomachs out of ten showed oocysts after 12 days eight in 53 were positive. Seven of the latter were heavy infections and exhibited ripe sporozoites—later shown to be infective by inoculation into chicks one of which developed parasites. On the fourteenth day the infection was successfully transmitted by biting (1 chick in 3 showing a patent infection) and also in a separate test by inoculation of the triturated mosquitoes in serum saline.

[The authors state that mosquito dissections do not have to be interpreted with care, because they may represent avian rather than human infections. In many parts of the world this would be unnecessary either because the known anopheline vectors are purely entomophilic in their habits (and thus unlikely to bite the wild birds) or precipitate control tests have already proved that their stomach contents do not contain a viable blood. In doubtful cases it is a simple matter to examine the blood in the stomach of the suspect species and see if it consists of nucleated corpuscles or not.]

RAOULT A Un cas d'anurie prolongée au cours d'une fièvre bilieuse hémoglobinnurique [A Case of Prolonged Anuria during Blackwater Fever] *Bull Méd del Afrique Occidentale Française* 1947, v 4, No 1, 43-8 1 folding chart

BURWELL, E L, KINNEY, T D & FINCH, C A Renal Damage following Intravascular Hemolysis *New England J of Med* 1947, Oct 30, v 237, No 18, 657-65, 5 figs [43 refs]

This paper is essentially a case report on a 29-year old woman admitted to hospital because of anuria following abortion and subsequent massive intravascular haemolysis. Three months after this episode, the patient died of homologous serum hepatitis. Autopsy afforded a unique opportunity to examine residual anatomical lesions in the kidneys three months after the anuric attack.

The kidneys were of normal size and shape, the capsules stripped readily, the surfaces were pale brown and firmly granular. The ratio of cortex to medulla was normal. Histologically, there was diffuse sub-capsular scarring with narrow bands extending deep into the medulla. There was some oedema of the interstitial tissue and focal collections of lymphocytes in the scarred areas. Most of the glomeruli were normal in appearance, but in the scarred areas there was some pericapsular scarring. Some of the convoluted and more particularly the collecting tubules, especially those in the outer zone, were dilated and the lining epithelium flattened. A few tubules contained hyaline casts, and sometimes desquamated epithelial cells. According to the authors, the pattern was such as to suggest the destruction of a single nephron or a group of nephrons.

The nature of the haemolytic reaction in this case was not discovered.

There is a discussion on haemoglobinuric nephrosis and its pathogenesis in general. The authors conclude that no one factor is solely responsible. The therapy of haemoglobinuric nephrosis is also discussed in relation to the case described. The authors stress that in the stage of haemoglobinuria and subsequent anuria the maintenance of blood volume and renal blood flow and a controlled fluid intake should be aimed at.

[As a clinical case report, this paper is interesting. It should have been confined to this. There is nothing new in the discussion on haemoglobinuric nephrosis. Reference to a great deal of relevant literature is omitted. For example the statement is made that "immediate alkalization is indicated in spite of the conflicting experimental evidence regarding its effects". In support of this dogmatic advice, with which the reviewer heartily disagrees, the reader is referred to one paper only, published in 1940. Work subsequent to this has been ignored.]

TRYPANOSOMIASIS

PELLISSIER, A. Particularités morphologiques des pièces génitales de *Glossina palpalis* Robinson, de *Glossina palpalis* Rob. Desc. var *fuscipes* Newstead, et de *Glossina tachinoides* Westwood, en Afrique Equatoriale Française. [Morphological Features in the Genital Organs of *G. palpalis* *G. palpalis* var *fuscipes* and *G. tachinoides* in French Equatorial Africa.] *Bull. Soc. Path. Exot.* 1947 v 40 Nov. 8/10 335-61 5 figs.

HOLLIS C. Streaky Blood Films. [Correspondence.] *Lancet* 1947 Dec. 20 928.

The author refers to a paper by BOWEN *et al* (*Lancet* 1947 Dec. 6, 831) in which it is stated that the streakiness in blood films gives a useful clinical indication of the plasma fibrinogen level, and, in most cases, of the corrected erythrocyte sedimentation rate.

The present author noted that in the blood of Africans with *Tryp gambiense* infections, the plasma albumin-globulin ratio is usually reversed, there is intense rouleaux formation and the blood sedimentation rate is much increased. With whole citrated blood, the B.S.R. did not change when it was repeated after re-mixing one hour later. If defibrinated blood was used (with or without citrate) the first B.S.R. was only slightly below that of the whole blood, yet on re-mixing after one hour both sedimentation and rouleaux formation had entirely disappeared. These results were obtained alike at blood temperature and at 0°C.

The author found one part of a 10 per cent. solution of suramin to 4 parts of blood to be an excellent anticoagulant which also inhibits rouleaux formation and sedimentation. It is suggested that these properties might have practical uses in haematology.

SIEGL A. L'aspect des maladies tropicales en Suisse. Deux cas de trypanosomiase humaine africaine. [Two Cases of African Trypanosomiasis contracted in Switzerland.] *Acta Tropica*. Basle. 1947 v 4 No. 4 298-311

This is a detailed record of two cases of accidental *T. gambiense* infections in laboratory workers at the Swiss Tropical Institute in Basle. The subjects were women aged 27 and 22, respectively and the infecting strains had been brought to Switzerland from Léopoldville and Brazzaville in 1945. One of them was arsenic-resistant. The earlier history of these strains is not given.

The patients were apparently infected not by accidental inoculation but by contaminating their fingers with infected blood, in the course of transmitting the strains through guinea-pigs. The onset in the first case was by a sharp attack of fever with headache followed by lassitude, insomnia, anorexia and an eruption of non-infiltrated, non-pruriginous erythematous spots on the skin of the abdomen. Trypanosomes were found in the blood 3-4 weeks after the onset of fever.

The second patient's illness began also with headache and fever lasting about a week, which then subsided for a month, but reappeared with headache and lassitude. Trypanosomes were found in the blood about two months after the beginning of the illness, by which time an eruption similar to that of the first patient had appeared on the abdomen.

Both patients were treated by combined atoxyl and tartar emetic followed immediately by suramin. A month after the end of treatment, one of them had a blood-positive relapse. She was then treated for 6 weeks with combined neostilbosan and suramin followed by pentamidine. The second patient received

a final 3-week course of combined tryparsamide and tartar emetic Both patients appeared quite well 3 months and 5 months, respectively, after discharge from hospital, but are, of course, to be kept under further observation

TRINQUIER, E & ARNOULT, H Premiers résultats obtenus avec la pentamidine dans le traitement de la maladie du sommeil en A E F
[Pentamidine Treatment of Sleeping Sickness in French Equatorial Africa]
Bull Soc Path Exot 1947, v 40, Nos 9/10, 388-400

The first cases of *T gambiense* sleeping sickness to receive pentamidine in French Equatorial Africa were treated in November 1945

Experience with this compound has confirmed that of other workers It is described as one of the best peripheral sterilizing agents known Early cases can be cured in 10, or perhaps even 5, days It has given excellent results in the treatment of relapses, or of cases refractory to other compounds In the late stages, however, it is inadequate, but combined with tryparsamide it gives results at least as good as those given by any other tryparsamide combination

SCHUELER, F W The Mechanism of Drug Resistance in Trypanosomes II
A Method for the Differential Staining of Normal and Drug Resistant Trypanosomes and its possible relation to the Mechanism of Drug Resistance
J Infect Dis 1947, Sept-Oct, v 81, No 2, 139-46, 2 figs [30 refs]

The author has compared the staining reactions of normal and of drug-resistant strains of trypanosomes at different hydrogen-ion concentrations

The trypanosome strains were (1) Normal *T equiperdum*, (2) *T equiperdum* resistant to mapharside and *p*-arsenosphenylbutyric acid, (3) Normal *T hippicum*, and (4) *T hippicum* resistant to pentavalent arsenicals

Two purely basic dyes were used, namely, methylene blue (Gruebler) and toluidine blue O (Conn) In some cases the trypanosomes were first treated with arsenicals, in order to study the effect of this on subsequent staining A purely acid dye, bluish eosin (Gruebler) was also used

The findings were interpreted as indicating that the acquirement of drug-resistance involves a significant shift in the isoelectric points of the trypanosome's proteins, particularly in certain localized portions of the trypanosome cell

E M Lourie

CULWICK, A T & FAIRBAIRN, H Polymorphism in *Trypanosoma simiae* and the Morphology of the Metacyclic Forms *Trans Roy Soc Trop Med & Hyg* 1947, Dec, v 41, No 3, 415-18, 1 fig

The authors describe the results of a biometrical study of the morphology of *Trypanosoma simiae*, the causative organism of acute porcine trypanosomiasis The strain which was used for this work was originally isolated from the blood of a horse in Tanganyika, then passaged through two sheep into tsetse-flies (*Glossina morsitans*), from which the trypanosomes were transmitted cyclically in *Cercopithecus* monkeys This study is based on the examination of blood films taken daily from these animals in the course of the infection, which lasted 4-6 days Attempts to infect goats with this strain failed

A statistical analysis of the measurements of this strain confirmed the reviewer's description of *T simiae* [this *Bulletin*, 1936, v 33, 647, 1937, v 34, 524] and showed that the species was trimorphic, comprising (a) long stout forms (*simiae* s s), which were predominant, (b) *rodhami*-like forms, and (c)

congolense-like forms. Since the long stout forms were the only ones dividing by binary fission, they are regarded as heteroxynous, while the other two are said to be homoxynous according to the authors' views regarding synangy in this trypanosome [this Bulletin 1947 v 44 649]

Metacyclic trypanosomes (which are depicted) were obtained on slides probed on by infected flies. They are represented by forms with and without a free flagellum measuring 10-12 μ in length. *T. sinuatus* was also discovered in the blood of cattle. It is thus present under natural conditions not only in its usual host, the pig but also in two new hosts—horse and cattle. In view of the superficial resemblance of some forms of *T. sinuatus* to *T. brucei* and of others to *T. congolense* equine and bovine infections with the first-named species are liable to be misinterpreted, unless the morphology of the trypanosomes present is carefully determined.

POMDE A. de A. with the collaboration of J. L. DE OLIVEIRA & others. A doença de Chagas na Bahia. [Chagas's Disease in Bahia.] *Arquivos Univ. Bahia Facul. de Med.* 1946 v 1 333-458, 107 figs. on pls. & 2 folding maps. [Refs. in footnotes.] Comments in English.

This monograph is a record of careful work carried out with close attention to detail. Cardiac disease is common in Bahia and the author who is a Professor of Clinical Medicine, has with the assistance of several colleagues, examined patients passing through the Cardiology Department of the Santa Isabel Hospital. His method of procedure was to examine those presenting suspicious symptoms oedema, cyanosis, dyspnoea, palpitation, cardiac enlargement, pleural effusion, ascites, hepatomegaly cardiac murmurs, praecordial pain etc., by X-ray by xenodiagnosis, and by complement fixation, using Davis's antigen. Ten species of *Triatomidae* are found in Bahia, but *P. megistus* seems to be the only important vector. Of 409 nymphs and adults 99 (24.4 per cent.) were found infected with *T. cruzi*. For the xenodiagnostic test 5-8 nymphs and adults were allowed to feed on the patients for on an average 30 minutes. Thereafter they were allowed to feed on chickens and guinea-pigs and were examined 30-60 days after the infecting feed.

Details are given of 37 cases with a number of cardiographic tracings of each, most of them well reproduced. In 11 out of 33 in which the xenodiagnostic methods were carried out the results were positive, a figure closely approximating that of ROMANA and CORRAO who found 34.6 per cent. whereas DIAS recorded only 14.15 per cent. The complement fixation test however gave a positive result in all 33 cases in which it was performed. In the other four xenodiagnosis was positive and the c.f. test was omitted.

The ages of the patients recorded ranged between 8 and 48 years, the majority being in the third and fourth decades and almost half (17 out of 38 whose ages were known) were between 1 and 30 years. The electro-cardiographic changes varied, the commonest being primary changes of the S-T and T waves and A.V. block.

There is a line map indicating the places whence patients came and where infected *P. megistus* were found and there are the usual photographs of children showing Romana's sign.

ROMANA, C. & ABALOS, J. *Triatoma delponteris* n. sp. (Hemiptera: Reduviidae) [*Triatoma delponteris* n. sp.] *An. Inst. Med. Regional Tucuman Argentina*. 1947 Nov. No. 1 79-93 7 figs. & 2 coloured pls. [14 refs.]

The English summary appended to the paper is as follows—

The authors describe *Triatoma delponteris* n. sp. infected naturally by *Schizotrypanum cruzi*. Their differential study is made with *Triatoma platensis*

Neiva 1913 *T. delponte* has been obtained exclusively in nests of *Miyopsitta monacha colorata*"

DE FREITAS, J. L. P. Contribuição para o estudo do diagnóstico da moléstia de Chagas por processos de laboratório [Laboratory Methods of Diagnosis of Chagas's Disease] [Thesis for Doctor's Degree] Universidade de São Paulo, Faculdade de Medicina -1947, 160 pp., 2 figs on 1 pl. [Bibliography] English summary

[This thesis is better than the usual run of theses for doctorate in Brazil Universities with which we have become acquainted. It differs much from the usual compilation from the literature for, though references to and quotations from published books and papers are copious, this thesis details a record of a considerable amount of work carefully performed by the author, though, naturally, it is repetitive rather than original.]

The various methods of diagnosing Chagas's disease are taken up in turn, the author has tried them himself in a fairly large number of cases and here puts his findings on record. First, *xenodiagnosis*. This was tested in 550 persons, and 93 (16.9 per cent) proved positive, of 1,025 Triatomidae which fed on patients suffering from Chagas's disease only 212 (20.6 per cent) were infected—not a satisfactory result—and one patient was tested no less than 14 times. Of 32 patients specially mentioned as undergoing the test three times, in 17 it was positive on the first occasion, in 9 on the second, and on the third in the remaining six. Second, *animal inoculation*, with the use of guinea-pigs and rats (camundongos). None of the former (8 only were inoculated) and only 4 of 238 of the latter, inoculated with blood from 38 patients, were infected. Third, *haemoculture* on blood agar was carried out from 21 patients, of whom 12 had given a positive xenodiagnostic test and the other 9 a positive complement fixation. At first, 0.2 cc of blood was inoculated but without result, so 0.5 cc was tried, but again all were negative. Fourth, *complement fixation*. The author divided the cases so tested into groups: (1) Those definitely infected with the trypanosome as evidenced by positive xenodiagnosis, by animal inoculation, or the finding of leishmania forms in the myocardium at autopsy. Of 75 in this group a strongly positive result was obtained in 71 and in two others it was weakly positive giving 97.3 per cent positive. (2) Those with lesions present or healed, of muco-cutaneous leishmaniasis. There were 44 of these and in all cases where the result was positive Chagas's disease was proved to be present also, or was strongly suspected. Where there was no such suspicion the result was negative, as it was also in group 3, syphilitic patients or those suffering from other diseases than Chagas's disease, such as malaria, soft chancre, blastomycosis, lymphogranuloma inguinale, glandular tuberculosis, and infectious mononucleosis. It is true that two patients with chancroid gave a positive c f test, but one definitely had Chagas's disease and the other lived in a district heavily infested with Triatomidae. In two among 34 with leprosy, in whom Chagas's disease could be excluded, the c f test was nevertheless positive. This test, even when the blood gave a strong positive, proved negative with the spinal fluid.

Other serological tests mentioned are the agglutination reaction, precipitin reactions with culture extracts, and the intradermal reaction with heart extract as reagent, which was negative in all cases tried.

The author concludes: "Xenodiagnosis is the best method to show the presence of *T. cruzi* in the blood of chronic cases of Chagas's disease. However, as in a large number of patients this test may be negative, the complement fixation test, employing *T. cruzi* antigen, is deemed the most valuable process for the diagnosis of the disease." [A praiseworthy and well documented piece of work.]

- ROMANA, C. & GI, J. Xenodiagnostico artificial. [Artificial Xenodiagnosis.] *An. Inst. Med. Regional Tucuman, Argentina.* 1947 Nov v 2, No. 1 57-60 1 fig

The English summary appended to the paper is as follows —

The authors describe a dispositive for practising artificial xenodiagnosis for cases in which it is not possible to perform it directly upon the patients. It consists of a tube closed with the skin of a laboratory animal which contains the suspected defibrinated or citrated blood. The triatomid bugs are placed in another tube in which is inserted the first mentioned. By this method they have obtained positive human xenodiagnosis."

- BARRETO, A. L. de B. Provas subsidiarias no diagnostico da doenca de Chagas. [Subidiary Tests in the Diagnosis of Chagas's Disease.] *Arquivos Univ. Bahia Facul. de Med.* 1948, v 1 285-320 [75 refs.] English summary

- ROMANA, C. Miocarditis cronica esquistotripanosica. (Hallazgo de *Schizotrypanum cruzi* en el corazon) [Chronic Myocarditis in Infection with *Trypanosoma cruzi*.] *An. Inst. Med. Regional Tucuman, Argentina.* 1947 Nov v 2, No. 1 1-18 15 text figs. & 2 coloured figs. on 1 pl.

The English summary appended to the paper is as follows —

"The clinical history is related of a patient with a supposed diagnosis of cardiac form of Chagas disease. In the autopsy there were found in the heart lesions of chronic infiltrative and sclerotic myocarditis and dividing forms of *S. cruzi*. In the epicardium and especially in the fibrous auriculo-ventricular circular band were observed great cellular accumulations in which the lymphoid cells predominate the true character of which is discussed in the text."

The English summary appended to the paper is as follows —

"The author after commenting on the present state of knowledge of the nervous forms of the Chagas disease relates the clinical history of three cases of chronic encephalopathy in which the only possible cause manifested was the *S. cruzi* infection."

"The patients present a syndrome of psychic states and of spastic paralysis which agree with the classical descriptions which Chagas and Villela gave for the nervous forms of the disease."

LEISHMANIASIS

- BALLABRIGA A. A propos des manifestations cliniques et des complications du kala azar infantile. [Infantile Kala-Azar] *A. n. Pediatrics* 1948, Dec. v 167 No. 6 364-72 5 figs.

The paper gives an account of 40 cases of infantile kala azar which the author had under her care in Barcelona during the past three years. The symptoms described are typical of the disease which is said to be quite common in Spain.

C. M. WYRON

Row, R & PATKAR, N A Kala-Azar of Undoubted Indigenous Origin discovered in Dry Areas *Indian Physician* 1947 Nov, v 6, No 11, 251-3

Report of a case from Bombay

MOST, H & LAVIETES, P H Kala Azar in American Military Personnel Report of 30 Cases *Medicine* 1947, Sept, v 26, No 3, 221-84, 10 figs [24 refs]

During, or as a result of, World War II, 50 to 75 cases of kala azar occurred in members of the United States Army. Most of these cases were studied very carefully and thirty came within the direct experience of the authors. These thirty cases form the basis of this paper, which is an excellent study of kala azar, primarily clinical in outlook. It will naturally be impossible to do it justice in a short summary.

Fifteen patients acquired the infection in India and 15 in the Mediterranean area, North Africa, Sicily or Italy, in the latter group was included a man who had served in London, Paris and Nice, the last for only one week three weeks before the onset of symptoms.

Most of the patients had spent nights in native villages within the endemic areas. Two officers lived in the same billet in Calcutta. [The reviewer was consulted by one of them in the U S A, and ascertained that these two officers shared a ground-floor flat in a part of Calcutta which he knew well as a highly endemic area.] The incubation period varied from 3 weeks in one case, to at least 19 months in another.

The onset was sudden, with fever, in 29 cases. The fever showed a double rise during the day in fifteen cases. One patient was afebrile throughout the observed course of the disease. Headache occurred in eight persons and was the commonest of the minor symptoms. Loss of weight was almost constant, but despite this and the fever, few of the patients appeared to be acutely ill at any stage of the disease. The tongue was not usually coated. In seven patients, cervical adenopathy was prominent, in 5, gland biopsy showed leishmania either at the first examination or on re-examination of the sections. No heart changes were noted.

The spleen was found enlarged in 27 patients at first examination, and in the other three enlargement developed later, 22 had enlarged livers at some stage of the disease. The spleen varied in size from being just palpable to reaching well below the umbilicus, the enlargement was very rapid, in some cases this level was reached within three months. There were no mental or neurological changes.

In almost every case malaria was suspected at first. The other febrile diseases considered were brucellosis in five cases, subacute bacterial endocarditis and military tuberculosis each in one case, dengue in two, typhoid or typhus in five, amoebiasis in three, pneumonia in two patients, one of whom actually had pneumonia also, infective hepatitis in two, histoplasmosis in one, nephritis in two and in nine cases, fever of uncertain origin (FUO) was the last diagnosis when the patients were transferred to a general hospital "after continued study and failure to establish a diagnosis." In addition to these, "Hodgkin's disease, acute aleukaemic leukaemia, aplastic anaemia and infectious mononucleosis were considered seriously in approximately 50 per cent of our cases, and in some patients one of these diagnoses was considered tenable for at least three months."

Sternal puncture was performed on 29 patients on one or more occasions, the first puncture was positive in 14, subsequent punctures in seven, and a negative puncture only was recorded in eight cases. Spleen puncture was performed on 18 patients and gave positive results in all.

The average period from onset of symptoms to diagnosis was 10 weeks and six patients were under observation in hospital from 4 to 8 months before a diagnosis of kala azar was made.

The drugs used were foinadin, neostam, stilbanose, neostibosan and stilbamidine and the percentage case cure rates were 0, 42, 50, 93 and 100. Foinadin and stilbamidine were used only in two cases each.

Neostibosan was given in total doses of 50 grammes in 10 to 17 days intravenously in a 5 per cent. solution. No toxic symptoms were observed. Toxic symptoms were observed in most of the patients who received neostam. The failures with neostibosan were usually due to inadequate dosage; one patient however after having had small amounts of foinadin, neostam and neostibosan overseas received two courses of neostibosan, of 5 and 10 grammes respectively and one of stilbanose without permanent improvement; he was eventually cured by 4.0 grammes of stilbamidine.

"Naper's formal-gel test" was positive in only half the cases in the first three months, but in 12 out of 14 after three months. The correlation with hyperglobulinæmia was not complete as occasionally, especially after treatment a clear firm gel (negative) occurred in the presence of over 4% per cent. of globulin. Electrophoretic studies were made and it was concluded that the globulin peculiar to leishmaniasis is a soluble gamma globulin which binds subnormal amounts of calcium. The authors suggest that it arises as an immune reaction or as a result of destruction of parasitized reticulo-endothelial cells.

Leucopenia and granulopenia were constant findings. 15 out of 23 patients had white counts below 4,000 per cmm. at the first examination and three out of 11 who were examined within the first 10 days of symptoms had counts below this figure. A count below 1,000 white cells or 500 granulocytes were encountered.

The red cell counts in 20 cases observed before treatment in the Moore General Hospital were all between 2.91 and 3.86 millions and within one month of successful treatment they ranged between 3.31 and 4.50 millions. The cells were usually slightly hypochromic and slightly macrocytic.

There was no marked prolongation of bleeding time or clotting time, but in a few cases clot retraction was retarded. The platelet counts were all subnormal, but extreme degrees of thrombocytopenia were not observed. Serum calcium was in the lower normal range.

The reticulocyte count was normally low before treatment and the authors claim that a significant crisis occurred in each of the six cases followed through treatment; the peak, which was over 10 per cent. in only two cases, namely 14.8 per cent. and 15 per cent. occurred between the 13th and 18th days after the first injection.

The erythrocyte sedimentation rate was usually but not constantly increased; it was not found of any value in predicting the activity of the disease.

There was no indication of liver dysfunction before, during or after treatment.

Out of 25 patients observed during an acute period of the disease 16 showed albumin in the urine, 12 macroscopic hæmaturia, and in two there were clinically important renal complications. There was one case of chronic renal insufficiency after successful treatment with neostibosan and in another a classical acute glomerulo-nephritis developed; this was approximately coincident with the onset of kala azar.

The paper includes individual case reports of these 30 cases.

The 24 references are 11 papers and books published in the United States or China; the vast literature that has emanated from Europe, North Africa, and India is ignored. [The reviewer's predominant impression on reading this important paper is that it demonstrates what an extraordinarily standardized

The question of the removal of the spleen has to be considered under four headings—namely its effect on the leishmaniasis, the anaemia, the leucopenia and the comfort of the patient. It was thought that the infection was possibly persisting in the spleen where it could not be reached in sufficient concentration by the anti-leishmania drugs. The persistent anaemia despite many blood transfusions might be produced by the enlarged spleen in several different ways—by providing a large haemostatic pool for blood and thereby increasing haemolysis—by providing an increase of reticulo-endothelial tissue which itself might increase blood destruction directly or indirectly by increasing the globulin in the blood and causing pseudo-agglutination and rouleau formation—or by splenic control of haemopoiesis. Hypersplenic conditions are also recognized as a cause of granulopenia. In this case the operation was successful on all four counts.

References in the literature to splenectomy in kala azar are discussed. These included two successful cases reported by MARTIN CHORINE and ROUSSEAU [this *Bulletin* 1936, v 33 30] and SWINNEY, FRIEDLANDER and QUINN [*ibid.* 1946 v 43 114].

L. E. A. JEFF

COLLARD P. J. & HARGREAVES W. H. Neuropathy after Stilbamidine Treatment of Kala-Azar. *Lancet* 1947 Nov. 8 686-8. (11 refs.)

A peculiar nervous sequel to the treatment of kala azar by stilbamidine was pointed out by NAPIER and SEN GUPTA [this *Bulletin* 1942 v 39 748]. This consisted of paraesthesia and anaesthesia of the face in the distribution of the trigeminal nerve. Later SEN GUPTA [*ibid.* 1944 v 41 273] reported it as occurring in 17 of 104 patients given the drug.

QASTLER and FIDLER [*ibid.* 1946 v 43 1029] reported that two patients treated for Sudanese kala azar by stilbamidine had died, late in convalescence from enal hepatic and pancreatic damage. Similar lesions were produced in dogs by the same solution, but no lesions were produced by a freshly prepared solution. However YORKE and FULTON [*ibid.* 1943 v 40 23] and FULTON [*ibid.* 683] showed that although the freshly prepared solution did not produce lesions in these organs, it did produce lesions in the central nervous system.

The present authors' first patient was invalided from Malta in November 1943 with kala azar—he failed to respond to two courses of neostam, but did so dramatically to a course consisting of 1.45 gm. of stilbamidine. A steady flow of cases of kala azar came in from North Africa, Sicily and Italy and stilbamidine was given in most cases with excellent immediate results—but by the end of 1944 an alarming number of cases with facial symptoms had been found during the follow up and subsequently this drug was replaced by carbostilamide and urea stilbamidine.

Of 4 cases in which stilbamidine was used, 22 developed the neuropathy 2 to 8 months after completion of treatment—the other two patients were not seen, but made no complaint of these lesions in their answers to a written questionnaire.

The symptoms were anaesthesia of the face and sometimes of the neck, scalp and chest; paraesthesia; hyperaesthesia so that light touch or shaving caused an agonizing pain; itching of the eyelids; watering of the eyes and blinking. The skin over the same area was sometimes dry and atrophic. The corneal reflex was depressed but never lost. The condition remained at its maximum up to 18 months and then gradually improved. No treatment had any effect. The disability was a serious one.

NAPIER and Sen Gupta [*loc. cit.*] suggested that the lesion was in the principal sensory nucleus of the trigeminal nerve and that it might extend caudally in the spinal tract. The authors consider that the lesion may extend further into the

central grey matter near the substantia gelatinosa Rolandi. The drug is related by its ethylene linkage to trichlorethylene, which also affects the cranial nerve nuclei, especially the fifth

L E Napier

MANGABEIRA-ALBERNAZ, P. Estudo critico do "pólipo da leishmaniose" [Critical Study of the "Leishmanial Polyp"] *Brasil-Médico* 1947, Aug 2 & 9, 16, 23 & 30, Sept 6 & 13, v 61, Nos 31-32, 33-34-35, 36-37, pp 283-91, 301-6, 319-23, 19 figs [70 refs]

The author more than 20 years ago described polyp of the nasal septum in leishmaniasis (*Ciência Médica*, 1925, v 3, 113 and *Arch Internat de Laryngol* 1926, v 32, 139) and under the title "the Leishmania polyp" in *Brasil-Médico*, 1928, v 42, 729) [In spite of this it is not mentioned in textbooks of Tropical Medicine, though STITT has a brief reference to oro-nasal leishmaniasis in his chapter dealing with leprosy]

In the present article, the author describes in detail and depicts in photographs and drawings four forms of the condition (1) The fibrous sessile type, (2) The peduncular mucoid type (3) The pendulous, the most common in which the tumour moves in the perforated septum, and (4) The diffuse hyperplastic. The histology is shown in a series of photomicrographs and the distinctions between this and tuberculous, syphilitic and other nasal tumours. On the scar or base of a leishmanial lesion a non-leishmanial tumour may grow. One illustration shows an angiofibroma which was removed from the nose and which had been growing from the edge of a leishmanial perforation of the septum. Twenty-eight cases are recorded in this paper

SMADL, J E, JACKSON, Elizabeth B & GAULD, R L. Factors influencing the Growth of *Rickettsiae*. I. Rickettsiostatic Effect of Streptomycin in Experimental Infections. *J Immunology* 1947, Nov v 57, No 3, 273-81, 1 fig [11 refs]

This study is in continuation of the investigation referred to in this *Bulletin*, 1948, v 45, 168

Strains of *Rickettsia prowazekii*, *R. mooseri*, *R. orientalis*, *R. akari*, and *Dermacentroxenus* [*Rickettsia*] *rickettsi* were cultivated in yolk sacs and employed in the tests in the usual way

Doses of 10-20 mgm of streptomycin produced an appreciable inhibitory effect on all the rickettsiae except *R. orientalis*, *R. akari* was most strongly affected. The addition of 0.4 mgm of nitroacridin to 10 mgm doses of streptomycin caused an additional degree of inhibition of growth of *R. mooseri*, and *R. rickettsi*, but not of *R. akari*. The addition of 0.5 mgm of para-aminobenzoic acid caused a pronounced degree of additional inhibition of growth of all the organisms except *R. orientalis*. These synergic effects are regarded as being of possible importance in connexion with treatment of the diseases

CAMAIN R. Sur une similitude d'affinités tinctoriales. Limitation des résultats donnés par la coloration des rickettsies au Machiavello et au Giemsa bouillant. [Limitations in the Results obtained by Staining of Rickettsiae by Machiavello's Method and Hot Giemsa.] *Bull. Soc. Path. Exot* 1947 v 40 Nov. 9/10 325-6.

The author examined the possibility of finding in certain micro-organisms inclusions having staining properties analogous to those of the ruby-red homogeneous bodies found in typhus material by GIBOURD and PANTHER [this *Bulletin*, 1942, v 39 753].

He used the routine stain employed in his laboratory namely boiling Giemsa and Machiavello to stain blood films from mice infected with *Trypanosoma gambiense*. In this way, he was able to demonstrate grains of volutin in the anterior part of the cytoplasm. Nevertheless, the author believes that the supposed affinity in staining properties between volutin and rickettsial bodies is only apparent because when the different processes in Machiavello's method are tested and analysed separately it will be seen that if the methylene blue counterstain alone is used, the rickettsiae stain pale blue but the volutin now stains violet black yet with combinations of fuchsin citric acid and methylene blue used in the full staining process, rickettsiae and volutin alike stain reddish purple. Since it is also known that the rickettsiae of scrub typhus take only the blue stain by Machiavello's method, the author concludes that, whatever the nature of volutin and of the inclusions in higher organisms tinctorially resembling it the use of Machiavello's method and of hot Giemsa do not provide a certain diagnostic criterion for detecting rickettsiae.

BIXAGHI G. Tifo esantematico benigno a Cagliari. [Mild Epidemic Typhus in Cagliari.] *Atta Med. Italiana* 1947 Oct. v 2, No. 10 327-9. English summary (3 lines)

An account of 24 cases.

MONTGOMERY T H L. & BUDDEN F H Typhus in Northern Nigeria. I. Epidemiological Studies. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1947 Dec. v 41 No. 3 327-37 2 figs. & 2 graphs.

An outbreak of louse-borne typhus occurred during the months June to September 1945 in Joo, a town of about 20 000 inhabitants situated at a height of about 4 000 feet on the Banchi Plateau North Nigeria. The cases detected numbered 128 of these 32 were fatal.

All the attacks occurred among persons living in 58 of the 1,600 compounds contained in the town. Louse infestation was heavy and almost universal.

In 92 cases, Weil-Felix titre of more than 1/100 was observed.

Despite early difficulties dusting with DDT powder soon became effective and when the people experienced the comfort of being free from lice and bedbugs they clamoured for the powder.

The authors stated that spare clothing, etc. after being dusted, were kept for 48 hours in closed dustbins no lice survived this treatment.

John W D Megey

FINDLAY G M. & ELMES B G T Typhus in Northern Nigeria. II. Laboratory Investigations. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1947 Dec. 41 No. 3 339-52. (14 refs.)

The authors describe their very thorough laboratory investigation into the outbreak of typhus fever referred to in the previous abstract.

Rickettsiae were isolated by guineapig inoculation from five out of seven batches (30-40 in each) of lice collected from patients, and from the blood of nine out of ten patients. Some of the human strains were passaged 7 to 20 times serially through guineapigs. In the early passages all the strains caused some degree of scrotal reaction, but after the 8th to 10th passages few reactions occurred, and none was observed after the 15th passage. Mooser cells were very occasionally seen in the tunica exudate. Rickettsiae were isolated from fleas (*Xenopsylla cheopis*) that had been caused to feed on a giant bush rat (*Cricetomys gambianus*) previously inoculated with one of the strains, but this observation was not regarded as showing that the strain was murine.

The sera of 92 patients gave high-titre agglutinations with *Proteus* strains—82 with OX19 and 10 with OX2. Of 31 sera tested for rickettsia agglutination, 27 gave higher-titre reactions with epidemic than with murine strains, the remaining four reacted more strongly with murine strains. Four sera were tested by the complement-fixation test, two reacted more strongly with epidemic than with murine antigens and two reacted at the same high titres with both antigens.

Various animals were tested for susceptibility to inoculation with suspensions of brains and spleens of infected guineapigs, the intraperitoneal route was employed except when otherwise stated.

In rabbits, a thermal reaction was sometimes produced, and in other rabbits inoculated intratracheally, fever and patchy pneumonia developed, rickettsiae were found in lung smears. Dogs showed no obvious reaction, but their blood on the 8th to the 15th day was infective to guineapigs. Out of seven green monkeys (*Cercopithecus aethiops centralis*) three gave a febrile response and their blood was infective to guineapigs. Another green monkey was inoculated intratracheally, a febrile reaction followed and rickettsiae were found in the lungs and blood. Eight other monkeys, belonging to four different species, were inoculated, there were no apparent reactions but the blood of two became infective to guineapigs. White mice were not affected by intranasal inoculation of the suspensions, but developed patchy pneumonia when suspensions of infected rabbits' lungs were used, and five successive lung passages were made.

Several kinds of wild rodents gave no apparent reactions, but infection was found in their blood.

The authors mention that flea-borne typhus is known to be widely distributed in West Africa and they refer to unpublished observations which strongly suggest that tick-borne infection also occurs. They state that rickettsiae were isolated from the blood of a European officer in Bauchi, Nigeria, and that his serum gave a positive complement-fixation reaction with a South African tick typhus antigen, but not with murine or epidemic antigens. The serum gave a negative rickettsia-agglutination reaction with epidemic and murine rickettsiae. Two similar cases are said to have occurred in North Ashanti.

A very puzzling case is described as occurring at Kaduna, 180 miles distant from Jos. Just before admission to hospital the patient found, attached to her scalp, a flat, oval, six-legged, "insect", about one-eighth of an inch long, brown in colour with diffuse mottling. At the site of attachment there was afterwards an eschar with local adenitis.

The rash was maculo-papular, it involved the palms and soles. On the 17th day the OX2 titre was 1-320 and the OX19 titre only 1-20.

The complement-fixation titre was found by Major J. Gear, S. A. A. M. C. to be 1-50 with each of four strains of epidemic antigen and 1-12.5 with murine and tick-borne antigens. Rickettsia agglutination was at 1-100 with epidemic and at 1-25 with murine strains.

Rickettsiae were isolated from the patient's blood in the earlier passages through guinea-pigs there was a pronounced haemorrhagic acrotal reaction, but this did not occur in the later passages. Cross immunity with the Jos strain was shown by guinea-pig inoculation.

No known case of rickettsial infection could be discovered from which the patient might have been infected.

The authors state that the history of an insect bite and the occurrence of an eschar suggested tick-borne infection and the behaviour of the strain in guinea-pigs suggested murine infection but the serological reactions were weighty evidence for an epidemic strain.

This is distinctly a problem case. Other points in favour of a tick-borne infection are the type and distribution of the rash, the OX8 type of Weil-Felix reaction and the absence of any evidence of other source of infection. Either of the two sets of conflicting evidence might be regarded as conclusive, but one must be wrong.

MONTGOMERY T. H. L. & BUDDEN, F. H. Typhus in Northern Nigeria. III. Clinical Studies. *Trans. Roy Soc Trop Med & Hyg* 1947 Dec., v 41 No. 3 353-62, 3 charts.

This paper contains a description of the clinical features of the outbreak referred to in the previous two papers. The authors state that the clinical picture did not conform to the classical text-book descriptions of louse-borne typhus in the following respects —there was complete absence of rash, diarrhoea, vomiting, gangrene, pressure sores, venous thrombosis, and pupillary contraction. (But the absence of a rash is quite usual among dark-skinned persons and the other features mentioned above are often missing in outbreaks of the disease.)

GOTTA, R. S. Contribución al estudio de la sedimentación globular en enfermos de tifo exantemático. (A Contribution to the Study of the Erythrocyte-Sedimentation Rate in Typhus Patients.) *Rev Inst. Salubridad y Enfermedades Trop* Mexico. 1947 June v 8, No. 2 97-117 11 charts. English summary.

The author describes the results of a systematic study of the changes occurring in the sedimentation rate at different stages of attacks of typhus fever. Of the 78 patients tested, 61 had classical, and 17 had murine typhus.

In most of the cases there was a progressive increase in the sedimentation rate till the end of the first week of convalescence and then a very slow return towards normal but many irregularities were observed. In mild attacks there was little or no departure from the normal. Complications gave rise to sudden increase in the rate. Among six fatal cases in which there were no complications, three showed no sedimentation, one showed a normal rate and in the other two the rate increased progressively till the day of death when a sudden return to normal was observed.

On the whole there was a direct relationship between the degree of increase in the acceleration of the sedimentation rate and the severity of the illness but there were striking exceptions to this rule.

The method employed was that described by CUTLER (*Amer J Med Sci* 1932, v 183 643). Illustrative curves and details of the average rates observed at various stages of the illness are presented.

RAVAT, J. H. Relationship between the Incidence of Typhus Fever among the Human and Murine Populations of Shanghai. *Chinese Med J Shanghai* 1947, July-Aug., v 65, Nos. 7 & 8, 211-24. [15 refs.]

Two papers by the same author dealing at greater length with the same subject have already been reviewed (this *Bulletin* 1947, v 14, 893, 1059).

IR, W. T., CHANG, I. L. & LIN, C. C. Typhus Fever in Chengtu. A Clinical Study of 184 Cases. *Chinese Med J Shanghai* 1947, July-Aug., v 65, Nos. 7 & 8, 199-210. 23 refs.

The authors saw 184 cases of typhus fever in two hospitals in Chengtu during the years 1940-1944. The great majority of the cases appear to have been flea-borne. The incidence month by month was as follows:—January, 10; February, 9; March, 9; April, 14; May, 7; June, 5; July, 9; August, 16; September, 37; October, 27; November, 27; and December, 14. There was no evidence of transmission to contacts except perhaps in a few extreme cases occurring during the winter and the spring among persons who had recently arrived in Chengtu after travelling from distant places.

Among the Weil-Felix tests that were carried out 75 patients gave positive reactions with *Proteus OX19*; of these, 59 also reacted with *OX2* and 7 with *OXA*. Three patients who gave negative reactions with *OX19* reacted with *OX2* at a titre of 1-160. *John W. D. Megaw.*

NYKA, W. Development of the Inflammatory Lesions and of Rickettsiae of Murine Typhus in the Lungs of Rats. *Inter J Path.* 1947, Sept., v 23, No. 5, 843-56. 12 figs. on 3 pls.

The histological changes observed in the lungs of rats sacrificed at intervals ranging from three minutes to 72 hours after inoculation by the nasal route with suspensions of murine rickettsiae are described.

The main part of the paper consists of a description of the development of the rickettsiae in the same lungs.

As early as five hours after inoculation, adult rods and diplococci are found, some of them in small intracellular clumps which are regarded as the earliest forms of rickettsial colonies developing from "dot forms" of the organisms. Later the clumps enlarge and rods and diplococci are seen to emerge from them and often to escape from the cells and enter other cells in which they continue to multiply.

After about 48 hours, pronounced extracellular multiplication is observed, associated with the formation of clumps which here as well as inside the cells sometimes grow to a considerable size. No evidence was found to support the view that invisible forms of the organism occur and the clumps are regarded as being nothing more than colonies of rickettsiae; there seemed to be no reason to assume that they represent a special developmental phase in the life cycle of the organisms.

The description of the multiplication of the rickettsiae is attractively simple, every statement is supported by a reference to one or more of the 32 clear photomicrographs which illustrate the paper. *John W. D. Megaw.*

JADIN, J. Fievre rouge congolaise ou typhus murin a Costermansville. [The Red Fever of the Congo or Murine Typhus at Costermansville]. *Bull Soc Belge de Méd Trop* 1947, June 30, v 27, No. 2, 231-40, 1 chart. [18 refs.]

Orchitic strains of rickettsiae, regarded as of murine type, were isolated from two out of five patients who were regarded as suffering from "fièvre rouge" (109).

PLAGUE

HENRY E. B. Laboratory Studies on the Bionomics of the Rat Fleas, *Xenopsylla brasiliensis* Baker and *Y. cheopis* Roths. III. Further Factors affecting Adult Longevity *Bull. Entom. Res.* 1947 Dec. v 38 Pt. 3, 399-404 [16 refs.]

The length of life of the adult *Xenopsylla* is of considerable importance in relation to the possible carriage of plague infection in merchandise also because one collection of data appeared to show a simple linear relation between length of life of the starved flea and saturation deficiency of the atmosphere. Since then large and puzzling anomalies have been recorded by HORSFORD [this Bulletin 1938, v 33 359], LAMSON [ibid. 879] and others. The subject seems to become less comprehensible as more work is done on it.

The present author has cleared up at least some of the anomalies. He shows that if the larvae (*X. brasiliensis* and a few experiments with *cheopis*) are reared together in a culture jar the adults live for a significantly shorter period than if the larvae are reared singly. Moreover old parent fleas lay eggs which give rise to adult progeny which are shorter lived than those of younger parents. Several other factors influencing the length of life of the starved adult flea are identified.

It is found that if the larval food is contaminated by the droppings of the mouse this has no significant effect on the length of life of the adult fleas (an unexpected result for the droppings would be supposed to be a source of B vitamins derived from micro-organisms presumably other material in the breeding medium provides these vitamins). Another unexpected but apparently well-established result is that unfed fleas live longer under several different standard conditions than those which have been fed once and then starved. [For previous papers in this series, see this Bulletin 1945 v 42, 504 1947 v 44 1103.] P. A. Buxton

SIMMONS, A. T. W. & CHENAIER, K. D. Further Observations on Plague. *Indian Med. Gaz.* 1947 Aug. v 82, No. 8, 447-51 3 figs.

DDT especially, seems to have been popular with villagers, because incidentally it got rid not only of fleas but also of bedbugs, flies and other pests. Curiously enough, the use of cyanogas and kerosene soap emulsion as an anti epidemic measure, formerly advocated is now regarded as "a too radical destruction of rats" and as having a merely ephemeral effect on fleas, so that on occasion it was followed by a sudden rise in plague incidence. W. T. Hurst,

KARASIMHANDI P. V. & RAO, K. S. Streptomycin in Human Plague. *Lancet* 1948 Jan. 3 22-51 g.

In this preliminary communication relating to an epidemic of 152 cases and 66 deaths, five moribund plague patients were treated with intramuscular streptomycin only. The dose was 0.125 gm. every 3 hours for 72-96 hours. Improvement was evident with a total of 1.5 gm.; no toxic effects were noted and all patients are now alive and well. Temperature charts and details are given. The five patients appear to have been the only cases treated as the supply of streptomycin became exhausted. W. T. Hurst

CHOLERA

- i. STRAUSS W. The Cholera Epidemic in Egypt and its Potential Danger to Palestine. *Harefuah*. Jerusalem. 1947 Dec. 1 v 33 No. 11 [In Hebrew 173-4 1 map. English summary 174]
- ii. SILBERSTEIN W. Preventive Inoculation against Cholera. *Ibid.* [In Hebrew 174-5. English summary 175.]
- iii. STEINITZ E. Notes on a Cholera Epidemic in Burma. *Ibid.* [In Hebrew 175-7. English summary 177.]

i. Measures taken by the Palestine authorities to limit the penetration of isolated cases of cholera from Egypt make the danger of the epidemic spreading to Palestine comparatively small. The author considers that the danger will increase at the end of the Egyptian epidemic when carriers may pass over the re-opened frontier. This eventuality must be met with the strictest measures to protect drinking water and food and the supervision of sanitation generally. It is considered that mass vaccination throughout Palestine would be premature, especially because of its uncertain and short-lived effects.

ii. The author discusses the theory and history of inoculation against cholera and points out that it is not analogous to anti-typhoid inoculation since the cholera vibrio is not brought into direct contact with the blood serum.

In Palestine at present the inoculation consists of two weekly injections (0.5 and 1.0 cc.) of a heat-killed vaccine containing 2 000 million organisms per cc. Reactions are sometimes severe. Pain and oedema where they occur usually last for 48 hours and general reactions are quite frequently severe comprising fever, nausea and vomiting, up to 72 hours. In about 10 per cent. of cases, there is transitory diarrhoea on the second day. It is made clear that preventive inoculation is only one of many preventive measures.

iii. A small cholera epidemic in Central Burma in August 1945 is described. Infection was traced to the indiscriminate drinking of water by Indian and African troops on the shallow shore of the Irrawaddy. Where dehydration was marked, colossal doses of intra-venous saline or glucose saline were given and relapses occurred if this fluid replacement was ceased prematurely. Milder cases were treated with sulphaguanidine. The author attributes the low death rate of 4 per cent. to immediate treatment, early inoculation and the probably low virulence of the vibrio. It is emphasized that effective treatment should always be given at the centre of an epidemic and that cholera patients should not be transported for long distances.

H. J. O'D. Burke-Gaffney

SHRIVASTAVA, D. L. & WHITE, P. B. Note on the Relationship of the so-called Ogawa and Inaba Types of *V. cholerae*. *Indian J. Med. Res.* 1947 July v 35 No. 3 117-29.

[An opinion might be hazarded that some bacteriologists especially those not engaged on definite investigation are none too satisfied with the validity of bacterial species generally. Statistically experience illustrates the powerful influence of selection technical selection the idea of transmutation seems to have something of the grip of a taboo when, to come closer to the subject in hand one found how paracholera vibrios tended to increase in number proportionately to the patience of the worker. One wondered whether failure to produce a greater number might have been reduced by more leisureed and assiduous study.] The authors have done great service to the controversy on the true cholera vibrio in declaring (1) their finding of mutants where dual serological types presented themselves in colonies (2) their belief in the possibility of races presenting trivalent agglutinative properties and (3) as a counter to a bacteriological stigma of complexity in taxonomy—their happier position of urging a simplification of ideas. In short they declare that the

system of subsidiary classification of *V. cholerae* at present in vogue—and in the popularization of which one of us has played some part—is, whatever may subsequently prove to be its practical importance, taxonomically invalid." The article must be read entire for its implications. Some of the summary may be quoted also —

(1) "From 10 strains of *V. cholerae* and 3 strains of *V. El Tor* belonging to the Ogawa type and grown in the presence of Ogawa mono-specific antiserum, there were isolated in each case races serologically indistinguishable from strains of the Inaba type" (2) "When similarly exposed to the action of mono-specific Inaba antiserum, 4 of 8 strains of *V. cholerae*, predominantly Inaba-like in serology, but possessed of an imperfect Ogawa factor, yielded cultures of the Ogawa type" (3) "The existing classification of the vibrios of 'O' group I into serological types is taxonomically invalid."

W F Harvey

BURROWS, W, ELLIOTT, Marian E & HAVENS, Isabelle. Studies on Immunity to Asiatic Cholera. IV The Excretion of Coproantibody in Experimental Enteric Cholera in the Guinea Pig. *J Infect Dis* 1947, Nov-Dec, v 81, No 3, 261-81, 9 figs [12 refs]

This is a fourth of a series of papers by BURROWS *et al* [this *Bulletin*, 1947, v 44, 422, 1948 v 45, 178]

Provision is finally made by the authors for clear understanding of a difficult argument in a discussion, a summary and a series of conclusions. Distinctions are drawn between intoxication through dosage and real infection, serum- and copro-antibody, local enteric and systemic infection, effective and non-effective immunity, secretion, excretion and leakage of immune body through the intestinal wall and permeability to antigen, apparent diminution in number of faecal vibrios due to agglutination and real diminution due to establishment of copro-immunization, diagnostic, prognostic and prophylactic implications, etc.

The original animal test of Koch by means of young guineapigs and alkalimination did not distinguish between toxæmia from overdose of the organisms and true establishment of infection. This has been declared capable of being a true infection by the authors, who show as much even as a 900 per cent multiplication of vibrios within the gut. At first, the strains of vibrio obtained were highly virulent and capable of giving rise to a fatal infection in the guineapigs but later it was no longer possible to produce real fatal infection. A non-fatal infection distinct from fatal toxæmia could, however, be produced and the guinea pig faecal pattern test with its similarity to human cholera infection provides a convenient tool for the study of this disease. The argument must be followed in all its detail. It was found by quantitative studies that — (1) the infection was enteric and this was not invalidated by ability to cultivate vibrios from the spleen though they were found there only in $\frac{1}{3}$ to $\frac{1}{2}$ of the animals. (2) non-fatal infection, originally fatal by inoculation of 25 mgm (50 000 million vibrios), could be produced with as little as 7 mgm of vibrios, (3) excretion of vibrios by the infected normal animal showed a characteristic pattern the vibrios making up 40 per cent to 90 per cent of the total faecal flora in the two to four days after infection. (4) alteration of the pattern in animals with a prior non fatal infection, or its equivalent of active parenterally produced immunity showed 'a sharp reduction in numbers excreted early in the infection to 10 per cent to 20 per cent of the total faecal flora and a reduction in time of persistence of infection'. The alteration did not occur in lethal infections where the percentage remained at 90 per cent or higher, (5) agglutinating and protective antibody but not bacteriophage could be demonstrated

in faecal fluid obtained by centrifuging and filtering through coarse paper. This antibody was called coproantibody and seems to have been identical with serum antibody although the mechanism by which it appears in the bowel and "contributes to immunity to enteric infection is not apparent from the reported experiments" (6) the coproantibody appeared early even before the peak of serum antibody and disappeared in 3 to 4 weeks although serum antibody persisted (7) an immunity-faecal pattern was presented when vibrio excretion was associated with the presence of coproantibody at the time of infection and the reduction of vibrio numbers was real. *W F Harvey*

MONTHLY BULL. MINISTRY OF HEALTH & PUB. HEALTH LAB. SERVICE
(DIRECTED BY MED. RES. COUNCIL.) 1947 Dec. v 6 225-9 Bacterio-
logical Examination of Stools for *Vibrio cholerae*

Laboratory workers in Great Britain will at least have to be prepared to recognise the true cholera vibrio in view of the possible introduction of the disease. Chronic carriers probably do not occur and the vibrio is not usually demonstrable for more than five days after onset. Attention will therefore be paid to the possibility of arrival of a patient suffering from the disease or a transitory healthy carrier who may possibly be in the incubation stage. Stools should be examined early and if delay occur should be suspended in the borate-saline mixture of VENKATRAMAN and RAMAKRISHNAN [this Bulletin 1942, v 39 458]. Direct cultivation is recommended on desoxycholate citrate agar and Aronson's medium, while Read's bismuth-sulphite modification of Wilson and Blair's medium may be used for enrichment. An inoculation intra-peritoneally of a loopful of an 18-hour peptone-water culture of the recently isolated vibrio should kill a young guinea pig in 24 hours, which distinguishes it from the non-cholera vibrios, except *V. mitsukurini* and the El Tor vibrio. No organism from a sporadic case of cholera in Great Britain should be identified as a cholera vibrio unless it is morphologically and culturally typical, falls into Heiberg's fermentative Group I, is cholera-red positive and Voges-Proskauer negative, fails to form a soluble haemolysin for sheep or goat red blood corpuscles and is agglutinated by an antiserum prepared against the specific O sub-group I of Gardner and Venkatraman. *W F Harvey*

ADISHANKAR R. PANDIT C G & VENKATRAMAN K V Statistical Evaluation
of Anti-Cholera Inoculation as a Personal Prophylactic against Cholera and
its Efficacy in the Prevention and Control of Cholera Epidemics. *Indian J*
Med Res. 1947 July v 35 No. 3, 131-52, 1 map & 1 graph.

As is the case with many if not most, prophylactic field operations there is, statistically the question of selection to be considered in assessment of the value of the data presented. There appear to be doubts about the effective exposure to the disease being identical in the case of the inoculated and uninoculated populations. Other considerations may cause difficulty in getting material for study even though total numbers may be large. Here for example the inquiry was contemplated only after thousands of inoculations had already been done and the test epidemic had become widespread. The vaccine used was almost invariably administered in single dose 1 cc. of vaccine containing 8000 million vibrios. The data required are (1) those pertaining to anticipatory inoculation which was taken to be inoculation done during the first outbreak in a village with respect to the second and subsequent outbreaks (2) the duration of the immunity conferred by inoculation (3) the influence of mass immunity on the occurrence of subsequent outbreaks. The investigation relates to rural areas only and the units were villages and

hamlets. A full statistical analysis has been carried out relating to 1.18 million persons in 2,350 villages who were inoculated with a vaccine containing both Inaba and Ogawa types of cholera vibrio. Altogether, in this very large scale operation, some 12½ million persons were inoculated. Of these there were recorded '1,118 cases of cholera amongst 709,977 protected persons in the inoculated population and 34,336 cases of cholera in 2,119,568 uninoculated persons.

Two or more outbreaks of cholera occurred in 627 out of 2,350 villages. In the second and subsequent outbreaks 6,589 cases of cholera occurred in the uninoculated group and 241 in the 'protected' group. That is the incidence in the uninoculated was 14.2 times greater than in the protected group. The other answers to the questions originally posed are that 'the immunity conferred by anti-cholera inoculation lasts for a minimum period of six months and probably remains effective up to 12 months' and 'Herd immunity seems to play an important part in preventing multiple outbreaks in a locality during an epidemic.'

W. L. HARRIS

CHANDRA SEKHAR C. Statistical Assessment of the Efficacy of Anti-Cholera Inoculation from the Data of 63 *Cases* in South Arcot District. *Indian J. Med. Res.* 1947 July v. 35, No. 3 153-70 3 figs. Appendix 171-6

Evidently the data collected by AMBESHAH, PANDIT and VENKATARAMAN (see previous abstract) were not wholly satisfying and an endeavour is made by the present author to study the facts for a more homogeneous population. For this he uses a smaller unit, the *Cases*, than the village or hamlet. It is a completely inhabited by the depressed classes, who are of the same social status, live close together, use the same water supply and eat the same food. Attention was concentrated on one district only and the definition, as before, of a second outbreak was 'one which took place at least 30 days after the first'. The result of this more searching statistical analysis seems to have been a reduction in the difference exhibited by inoculated and uninoculated.

The attack rate in the not inoculated population was found to be 2.4 times that in the inoculated population. Statistical test indicated that inoculation against cholera averted the disease and was useful as a personal prophylaxis. Although the average resistance of the population was increased by inoculation, there was no significant difference between the case-fatality rate against the attack of the inoculated and not inoculated populations.

W. L. HARRIS

New Delhi, despite the difference in the incidence of amoebiasis. It is concluded that these moderately severe diarrhoeas are not necessarily amoebic in origin and that the incidence of amoebiasis of 20 per cent. is probably coincidental. It is also suggested that pathogenic bacteria, and those that may possibly be so may play an important role in determining a person's resistance to amoebic infection and may also constitute an accessory factor in determining the power of penetration through the intestinal mucosa by *Entamoeba histolytica*.

BINGHAM, J. A. W. Perforation of the Colon in Dysentery. Two Cases of Recovery after Operation. *Lancet.* 1948, Jan. 24 139-40.

Two cases of perforation in dysentery recovered after operation. One was an amoebic case, treated by colectomy, and the other a Flexner's bacillus infection treated by drainage of a pelvic abscess.

BOCK, H. E. Lebervergrößerung bei oder infolge Lambliosen und Amoebiasis. (Zugleich ein Beitrag zur Frage der parasitär-enterogenen Hepatopathie und der Amöbenhepatitis.) [Liver Enlargement from either Giardiasis or Amoebiasis.] *Arch. Woch.* 1947 Mar 1 v 24-25 Nos. 21/22, 331-7 5 figs. [24 refs.]

In this rather discursive communication it is difficult to distinguish the main object. There appears to have been some doubt in the minds of German diagnosticians between the hepatomegaly of infective and amoebic hepatitis. As Giardia cysts were found in 8 per cent. and *E. histolytica* in 8.5 per cent. of the cases of liver enlargement considered, it was possible that in some there was a double infection.

The author claims that the early stages of amoebic hepatitis can be recognized by a positive Takata reaction as well as by vacuolation of the hepatic cells in material obtained by liver puncture. Additional evidence is afforded by increased blood sedimentation rate, leucocytosis with a shift of the Arneth index to the left, in addition to hepatomegaly.

Response to the therapeutic action of emetine is very suggestive of the diagnosis of hepatic amoebiasis, but apparent cure may be deceptive and abscess formation may occur after it. Three instances are recorded in which after apparent satisfactory response to emetine therapy all ascertainable signs and symptoms (with the exception of a positive Takata reaction) disappeared and yet an abscess cavity was proved to exist by hepatic aspiration.

BANKER D. D. Amoebic Abscess of the Liver. *Indian Physician* 1947 Nov v 8 No. 11 254-62

This paper comprises a study of 130 cases of amoebic abscess of the liver seen during a period of ten years up to December 1944 and 66 cases diagnosed at autopsy. Making allowances for 12, which were included in both series, grand

total of 184 cases is obtained. Only those have been included in which confirmatory evidence was obtainable by the demonstration of typical liver abscess pus. Approximately one case in every 1,000 admitted to the K E M Hospital in Bombay turned out to be a liver abscess.

Once more a marked preponderance of the disease in the male is evident. Of the 130 patients, 97.7 per cent were males, and this is in accordance with the observations of workers elsewhere. In the present series there is no record of cases in infancy or childhood. On the other hand, the minimum age was 18 and the maximum 62, and the maximum incidence lies between the ages of 30 and 50 years. The greatest incidence was amongst the poor labouring classes.

Previous attacks of "dysentery" were recorded in 40 per cent. In 3 per cent only did dysenteric symptoms coincide with liver abscess, in the great majority, the interval between them was from 2 months to 5 years. It was not possible to record previous attacks of amoebic hepatitis. Pain in the right hypochondrium was present in 65 per cent of cases and the most prominent symptoms were pain and swelling in the same area. Shoulder pain, ocular icterus and persistent hiccough were exceptional. The commonest sign was tenderness in the right hypochondrium in 95 per cent. Enlargement of the liver was verified in 83 per cent.

Radiological screening of the diaphragm was carried out in 27 and raising of the right dome and immobility was demonstrated in all. In one only was a central circular dense area suggestive of an abscess cavity demonstrated. In 86 per cent the leucocyte count was above 10,000 per cmm.

As regards the abscess contents in 78 per cent the pus was typically chocolate-coloured and in the remainder brownish yellow. Trophozoites of *E. histolytica* were seen on two occasions only.

Two chief lines of treatment were carried out. (1) One or more aspirations combined with emetine injections. In all, 75 cases were thus treated and in 30 aspiration had to be repeated. (2) Incision and drainage combined with emetine injections were carried out in 32. In 27 cases the approach was trans-thoracic with rib resection, in the remainder it was trans-abdominal. The case mortality for all treatments was 29 per cent, but for aspiration and emetine it was 13.3 per cent. Where the abscess had perforated the mortality was higher—in 14 such cases, 10 proved fatal. After open operation in 32 cases there were 9 fatalities.

Relapses were recorded in 6 per cent.

Complications. Perforation was most frequent and was fatal in 71 per cent of cases [already shown as 10 out of 14].

Perforation into the right lung occurred in three, two of which healed spontaneously. Into the peritoneal cavity there were four of which three proved fatal. There were 4 perforations into right pleural cavity (three fatal) and one fatal perforation involving peritoneal and right pleural cavities together. Perforation of the abdominal wall occurred in two cases, both of which were fatal.

In six cases, secondary infecting organisms were isolated.

In 22 cases out of 66 at autopsy more than three abscesses were seen in each, in the remaining 34 (52 per cent) the abscess was solitary.

The largest abscess was 18 cm in diameter, four of them were small, being less than 1 cm.

Concurrent amoebic ulcers in the large intestine were found in 51 cases at autopsy, in the other 15 no such lesions were seen.

In 24 cases, the whole of the large intestine was involved. The caecum alone, the caecum and ascending colon and the ascending colon alone were each involved 8 times, and the pelvic colon and rectum three times. Concurrent

ulcers were more common in the proximal portion of the intestine and this coincides with the universally held view that amoebic liver abscess is more likely to occur in the right than in the left lobe. The cause of death ascertained at autopsy was perforation in 21 cases, extensive destruction of the liver in 14, perforation of amoebic ulcer in the intestine in 6, secondary lobar or bronchopneumonia in 6, and active pulmonary tuberculosis in 4. *P. Manson-Bahr*

RESTREPO R. & MENDOZA LEMAITRE, A. Infecciones amebianas confundidas con cáncer. Amibiasis del cuello uterino y vagina diagnosticada como cáncer uterino anizado. Amibiasis de la vulva. [Amoebic Infection confused with Cancer of the Cervix Uteri and the Vulva.] *Rev. Facul. de Med. Bogotá*. 1947 Sept., v. 16, No. 3 914-20 4 figs.

AMADOR, M. Uremia extrarenal causada por *Endamoeba histolytica*. [Extrarenal Uraemia due to *Endamoeba histolytica*.] *Medicina*. Mexico. 1947 Nov. 25 v. 27 No. 544 315-21 [19 refs.]

Much of this article is taken up with redundancies, recording matters generally known such as the physiology of protein metabolism, the function of the liver in the formation of urea, the history of *E. histolytica* and its cultivation, Craig's recording of the presence of nephritis in fatal cases of amoebic dysentery in the Philippines in 1904. Apart from all this the author's thesis appears to be that *E. histolytica* needs an alkaline pH, and NaCl for its development in the body; that living in the large intestine the parasite is subjected to a varying pH according to the food taken and the intestinal flora, that a meat diet renders the faeces alkaline and so facilitates the metabolism of the amoeba, and that increased call is made on the liver to exercise its rôle of detoxicant.

In a case detailed the patient had been dieting for 12 years on account of supposed renal disease and a threatened uraemic state. His blood urea was 40 mgm. and had been 75 mgm. and diet practically meatless had little effect on it; chlorides in the blood were below normal. Cysts of *E. histolytica* were found in the faeces. He was given specific treatment with carvacrone and later was eating meat daily. The blood urea fell to 23.07 mgm. and his blood pressure from 210/110 to 150/90.

The author concludes that the hyperazotaemia in chronic amoebiasis results from preceding deficiency of chloride and is not the result of disturbance of renal function or pathological changes in the kidneys.

BENHAMOU E. ALBOU A. & LEONARDON H. A propos du traitement de l'amibiose intestinale par l'association pénicilline-sulphaguanidine-émétine. [Treatment of Amoebic Dysentery with a Combination of Penicillin, Sulphaguanidine and Emetine.] *Algérie Méd.* 1947 Oct. v. 50 No. 8 608-11

The authors refer to the work of HARGREAVES [this *Bulletin* 1945 v. 42, 895] and BLANC and SGUIER [ibid. 1947 v. 44, 524] on the treatment of intestinal amoebiasis with penicillin and sulphonamides in addition to emetine, as means of combating secondary infection.

They themselves have used this type of combined treatment for 3 patients in Algiers, with very satisfactory immediate results.

One patient suffered from amoebic dysentery only, the other two had in addition, bacillary dysentery and *P. falciparum* malaria respectively.

Varying combinations of the drugs were given over periods of 4 to 7 days, these included from 1 to 2 million units of penicillin, from 80 to 100 gm. of sulphaguanidine and either 0.37 to 0.58 gm. of emetine or 4 to 5 gm. of stovarsol.

The authors note that the cases of Blanc and Siguer were all severe, of a type seen in tropical climates in Algeria, on the other hand, mixed infections are not usually severe and amoebiasis responds to classical treatment it is therefore suggested that the value of a new method in these cases must be assessed on the long-range prognosis, rather than on immediate results, particularly in relation to relapses This must take into account the "*notion de terrain et de milieu*", since persons living continuously in a tropical environment where they are constantly exposed to amoebic re-infestations and secondary infections may have little chance of permanent cure these factors do not operate in Algeria, so that, with appropriately adjusted dosages, it may be that something more effective and permanent than the classical treatment may be found in the use of synergic methods

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

CHORINE V & COLAS-BELCOUR, J. Perte du pouvoir infectant des cultures de *Spirochaeta hispanica* pour l'*Ornithodoros erraticus* son vecteur dans la nature. [The Loss of Infectivity of Cultures of *Spirochaeta hispanica* for *Ornithodoros erraticus* its Natural Vector] *Bull. Soc. Path. Exot.* 1947 v 40 Nos. 9/10 383-8. [11 refs.]

The study of cultures of *S. hispanica* has shown that there is a gradual diminution in virulence as the number of passages increases, but this diminution is less evident in rodents than in human subjects. Even after 80 passages, 0.01 cc. of a culture will infect a guinea-pig although the incubation period is increased from 2 to 14 days and the resulting infection is benign.

Various lots of *Ornithodoros erraticus* were fed through artificial membrane on suspensions of the culture spirochaetes and after varying intervals allowed to feed on normal guinea-pigs. In addition ticks were ground up and inoculated into other guinea-pigs. The results were uniformly negative, neither infection nor immunity being shown by any of the animals. Finally ticks were fed on rabbits that had been inoculated intravenously with 75 cc. of a rich culture of spirochaetes, immediately before the experiments. These ticks also gave negative results when tested for infectivity.

The results show that in culture *S. hispanica* loses its infectivity for the transmitting host before its power of infecting vertebrate hosts. The authors consider that this resembles the loss of infectivity to the transmitting host shown by certain strains of Protozoa that have been maintained artificially in the laboratory by passage in the vertebrate host without the intervention of any arthropod vector. Various trypanosomes after a certain number of passages lose their infectivity for *Glossina*; certain strains of *Plasmodium vivax* after being maintained for some years by inoculation from one human patient to another lose their power of developing in *Anopheles*; finally *Theileria dispa* after passage in bovines for 6 years will no longer develop in the intermediate host *Hyalomma marginatum*.

DECAOP. Typhus récurrent et rougeole. [Relapsing Fever and Measles.] *Cahiers Méd. Union Française Algérie*. 1947 June 2, No 11 457

Report of case.

JERSON W F. Economic Control of the Relapsing Fever Tick in African Houses. [Correspondence.] *Nature*. 1947 Dec. 20 874.

Ornithodoros moubata is alarmingly abundant in many townships and labour camps in East Africa. It is markedly resistant to the common insecticides and its control has hitherto proved uneconomic.

The author, who is an entomologist in the Tanganyika Territory Agricultural Department, has been impressed with the outstanding toxicity of hexachloro-cyclohexane to *O. moubata* and has had very promising results in practical trials with a number of Gammaxan formulations.

In laboratory tests the lightest dusting of individual ticks with 0.5 per cent. Gammaxan caused them to lose co-ordination of leg movements in 4 to 8 hours and to lose up to 10 per cent. of body weight in 24 hours by loss of fluids. Immobility apart from feeble but persistent leg movements, occurred in 12 hours to 5 days according to age and 80 to 100 per cent. mortalities resulted in 8 to 10 days. Adult ticks, especially gravid females, showed leg movements up to 2 months after treatment but all eggs laid failed to hatch.

Dusting with 5 per cent DDT is slower and less effective, but mortalities of 50 to 80 per cent were obtained after more than 20 days

In the field, 0.5 per cent Gammexane dust was most economic when applied, with a simple shaker such as a round tin, to the floors and first few inches of the walls of infested houses, the application was made at 3 to 4 lb of dust per 1,000 sq ft of surface. Results were checked by five "boys" who searched the floors to a depth of 1½ inches at random for 5 minutes. In this way, infestation in a labour transit camp was reduced from an average of 20 per unit sample to less than 0.2 over a period of nine months, after this period, further treatment was necessary, possibly because of regular re-infestation from transit labourers. When the commercial dust concentrate (2.5 per cent Gammexane) was diluted with a local diluent (preferably a light diatomaceous earth, "Diatomite"), the cost of the material was about 4.5 pence per lb which is well within the economic range for large-scale use.

Extended experiments have been started in a whole township of about 1,200 houses half of them are infested with *O. moubata*, with a consequent high incidence of relapsing fever the reduction of ticks is already appreciated, although it will be some time before the relapsing fever statistics can be assessed.

It is added that this treatment has been officially standardized in several Government departments in Tanganyika as an advance on any previous control measures [see also this *Bulletin*, 1947, v 44, 1070]

LING, C C. A Preliminary Study of the Treatment of Chinese Louse-borne Relapsing Fever with Penicillin. *Chinese Med J Shanghai* 1947, July-Aug, v 65, Nos 7/8, 225-30 [10 refs]

"A preliminary study of two cases of Chinese louse-borne relapsing fever treated with penicillin was made. It was found that penicillin given late in the paroxysm did not shorten the duration of the paroxysm, but prevented relapse and effected cure. When penicillin was administered on the first day of paroxysm, a rapid induced crisis resulted. The arbitrary doses employed were 960,000 and 1,780,000 units, and both were found to be adequate to eradicate the infection. The indications of penicillin therapy in relapsing fever are briefly outlined."

YAWS

ARJE, S L. Yaws treated with Single Massive Doses of Penicillin. *U S Nav Med Bull* 1947 Nov-Dec, v 47, No 6, 965-9, 3 figs

In islands outside the Truk atoll, between October 1946 and June 1947, some 5,000 cases of yaws were treated with a single injection of penicillin. At first 200,000 units of sodium penicillin in 4 cc of sterile water was used, but later this was replaced by 300,000 units of calcium penicillin in 1 cc of beeswax and arachis oil. Cases were observed at intervals of 1-2 months for 9 months.

The total numbers of new cases and clinically active yaws were reduced, the typical secondary skin lesions were reduced to a greater extent than plantar granulomatous yaws.

This treatment was in use until adequate trained staff became available, but inadequate cold storage facilities then caused penicillin to be replaced by "mapharsen" [No serological data are reported]

GUIMARÃES, F. V. Pesquisas sobre a imunidade da *Framboesia* tropical no homem. Observações feitas em 33 superinoculações e 7 reinoculações. [Immunity in Yaws: Studies of 33 Superinoculations and 7 Reinoculations.] *Mém. Inst. Oswaldo Cruz*. 1948, Dec. v 44 No. 4 649-85 6 figs. & 10 pls. English summary

This study is based upon superinoculations in 33 Wassermann-positive yaws patients and reinoculations in 7 Wassermann-negative treated yaws patients.

From 2-8 months after infection attempts at superinoculation with yaws spirochaetes were usually unsuccessful. This was independent of the presence of primary or secondary skin lesions. Treatment during this period abolished this immunity.

From 10-18 months the resistance to superinfection decreased and localized lesions resembling non-granulomatous secondary skin yaws, planides or desquamating papular areas resulted, without generalized lesions, for at least 4 months later. This response seemed to be independent of the presence of active yaws and is not altered by treatment resulting in clinical cure and negative Wassermann reactions.

After the 5th year superinfection caused a necrotic ulcer together with an exacerbation of any other lesions present (tertiary gummatous in most of the cases studied) and swelling of satellite glands. No generalized lesions followed (in one case after 18 months). Treatment had no effect on the response. Three patients with tertiary gummatous lesions, but with yaws of less than three years duration, did not give this response. These necrotic lesions contained only few treponemata. Their histopathology was similar to that of tertiary yaws. [In these cases the incubation period of inoculation lesions was shorter than in the previous group 8-10 days against 20-30 days.]

Epidemiologically it is advisable to wait until the end of the generalized secondary stage of yaws before beginning treatment, since reinfection is possible but from a preventive point of view early treatment to reduce the source of infection is essential.

In yaws there is a true immunity since the response to reinfection is unaltered by treatment. This immunity is manifested by resistance or modified response to superinoculation or absence of generalization. These different immunity states may condition the different manifestations of yaws. In yaws, immunity is related to age of infection, the virulence of the organism and the individual characteristics of the patient.

[These findings are interesting and might usefully be extended.]

LEPROSY

DE SOUZA-ARAÚJO, H. C. & ROSSINI, C. S. C. Isolamento de bacilos ácido-alcool resistentes das águas dos efluentes das fossas OMS do Sanatório Padre Bento (S. Paulo) e do Hospital-Colônia Curupaitv (Distrito Federal). [Isolation of Acid-Alcohol-fast Bacilli from the Effluents of a Sanatorium in São Paulo and a Hospital in the Federal District.] *Mém. Inst. Oswaldo Cruz*. 1948, Dec. v 44 No. 4 763-71 3 figs.

The authors obtained samples from the drainage effluents of the Leprosarium Padre Bento São Paulo, and the Hospital-Colônia Curupaitv, Distrito Federal. The samples had been collected and centrifuged, the deposits were centrifuged, the treated by the Petroff method and again three centrifuged, the

deposit washed and sown on Loewenstein's medium Smears of the deposit showed bacilli which were acid- and alcohol-fast Several weeks later, growth was obtained which appeared to be identical with those which have been described as having been isolated from leprous material In an addendum, Dr Roßsell records isolating the same (or a similar) organism from the effluent of another leprosarium in South Minas [see this *Bulletin*, 1945, v 42, 566, 1006]

IGNACIO CHALA H, J Comentarios sobre clasificación de la lepra Manifestaciones dermatológicas y nerviosas del tipo tuberculoide [Remarks on the Classification of Leprosy Cutaneous and Nervous Manifestations of the Tuberculoid Form] Reprinted from *An Soc Biol Bogota* 1947, May, v 2, No 6, 216-28, 8 figs

The author discusses the validity of the classification of cases of leprosy into lepromatous, tuberculoid and non-characteristic He describes the division of the tuberculoid type (as recommended at the Cairo Congress in 1938) into the reactional and the quiescent and describes each fully The "non-characteristic" cannot be, at all events ought not to be, considered a type in the same sense as either of the others The lepromatous patient, however, free from clinical symptoms, always harbours the bacillus in the lymph of the glands and is, therefore, a danger to the public and should never reach the class of the socially cured allowed out on parole

Among 513 patients studied, 48 (9.35 per cent) were of the tuberculoid type 206 (40.1) lepromatous, and 259 (50.5) non-characteristic The author regards, the last as undergoing an evolution stage of the disease which cannot be looked upon as a form or type of leprosy as it may evolve into one or other definite type By examination for Hansen's bacilli and by testing the Mitsuda reaction at intervals such patients can in time be relegated, he maintains, to their proper category In the true tuberculoid type, the reaction is strongly positive, in the true lepromatous definitely negative, in the non-characteristic it varies and may be negative or weakly positive

MONTESTRUC, E & CAUBET, P Ainhum lépreux localisé au cinquième doigt [Ainhum of the Little Finger in a Patient with Leprosy] *Cahiers Méd Union Française* Algiers 1947, Nov, v 2, No 14, 667, 1 fig

THIROUX and DELAMARRE are mentioned as having observed anhum and leprosy co-existing in the same patient [no reference is given] A photograph reproduced in the present note shows leprous mutilations of the fingers of both hands and anhum of the right little finger The authors state definitely that "it is impossible, in this case, not to ascribe the anhum as due to leprosy", but in another place state more guardedly "leprosy may not always take part in the production of lesions like this" and conclude that anhum, goundou and perforating ulcer of the sole are not due to one single cause, but have a mixed aetiology

H Harold Scott

MONTESTRUC, E & RAGUSIN Le goundou lépreux Considerations étiologiques sur le goundou [The Aetiology of Goundou, Leprosy as a Cause] *Cahiers Méd Union Française* Algiers 1947, Nov, v 2, No 14, 665-6

Authors are by no means unanimous in ascribing goundou to yaws, some say they see no cases in places where yaws is common and others report cases as rare in highly endemic yaws districts The present authors record a case in Martinique The patient, a woman 27 years of age, was suffering from leprosy

and showed typical goundou nasal tumours. Hansen's bacilli were present in the nasal mucosa and in biopsy material of a tubercle the W.R. was negative and no history indicative of yaws was obtainable.

They quote HIRSCHBERG and BIRHLER [but do not give the references] as having published an important work on osseous leprosy and say that the former mentions bony lesions of the upper jaw and of the bones of the nose. They also mention HIRIVAUX as having shown to the Medical Society of Madagascar in 1930 a patient suffering from mixed leprosy with goundou-like tumours on each side of the nose which he called *pseudo-goundou* and added that the patient was "free from yaws".

DE SOUZA ARAUJO H. C. "Ação bacteriolítica da Tyrothricin" em relação às culturas de bacilos ácido-álcool resistentes isolados de leprocos e sua ineficácia como agente terapêutico da lepra humana. [Action of Tyrothricin on Cultures of Bacilli Isolated from Leprosy Patients and its Use in Treatment of Human Leprosy] *Mem. Inst. Oswaldo Cruz.* 1948 Dec., v 44 No. 4 749-61 2 figs.

Tyrothricin a mixture of gramicidin and tyrocidin obtained from cultures of *Bacillus brevis* a sporing aerobic saprophytic Gram-positive organism, has been recommended as an antibiotic, bacteriostatic and bacteriolytic, like penicillin. The author obtained a 1 per cent. solution of it in 95 per cent. alcohol and prepared numerous dilutions from it in glycerinated broth. He then set up a series of tubes, inoculated them with various cultures of acid-fast bacilli isolated from leprosy patients or insects which had been fed on them, and found it to be bacteriostatic in dilutions of 1:8,000 and 1:16,000 with different bacteria. He then proceeded to try it, intradermally injected, in cases of leprosy and four cases are reported in considerable detail day by day. Only the general results can be recorded here for those interested a study of these details should prove very informative. Tyrothricin proved to be a marked local irritant but it increased phagocytosis and local reaction was marked there was some systemic disturbance and the patient might say that it made him feel ill and he would ask to have the treatment changed. In spite of its action *in vitro* it had no curative action in these patients and did not prevent the development of fresh lepromata and macules later nor did it bring about any regression of the disease.

HELMINTHIASIS

MEIRA, J. A. Esquistosomíase Mansoní. Subsídio ao estudo de sua incidência e distribuição geográfica no Brasil. Lista bibliográfica brasileira sobre a esquistosomíase mansoní (doença de Manson-Pirajá da Silva). [Schistosomíase Mansoní. Halpe to the Study of its Incidence and Geographical Distribution in Brazil, with a Bibliography]. Reprinted from *Arquivos Facul. de Hig. Saude Publica U. de São Paulo* 1947 June v 1 No. 1 146 pp. [Bibliography]

This full and painstaking account of *Schistosomum mansoní* in Brazil drives home the fact that the infestation is very widespread, is of great economic as well as of medical importance and calls urgently for more intensive measures of control. The work is divided into three main parts. The first, of an introductory nature points out in more or less general terms the gravity of the problem the unsatisfactoriness or inaccuracy of the returns hitherto regarding prevalence and the almost universal (that is, in Brazil) presence of species of

Helminthiasis

Vol 45, No 4]

Australorbis, the chief snail host In this section, the prevalence in the different States is hinted at, the detailed accounts of each of 21 States occupies part II, which constitutes the greater portion of this work. Other hosts than *Australorbis glabratus* (*Planorbis centumetralis*) are *P. guadalupensis* and *P. olivaceus*, a considerable percentage of which are found to harbour cercariae, in Ceará, for example, 17.9 per cent of 307 examined.

Space forbids our recording here the findings in the different States, but as an example we may deal more fully with Pernambuco, to which several pages in the work are devoted. Viscerotomy specimens were obtained from 5,202 persons in 40 localities, and 763 (14.6 per cent) were positive. The percentages varied greatly, in Jardim and Duarte Dias none was found, but only small numbers, 17 and 35 respectively, were examined, in Palmares the positives were 35.9 per cent of 114. Pontezinha, near the river Jaboalão, has a population of 1,200, 1,010 of these had their faeces examined, once only, and the percentage incidence by age [actual numbers are not stated] was under 5 years 2.7, 6-10 years 12.1, 11-15 years 30.8, 16-20 years 37.8, 21-30 years 30.7, 31-45 years 24.8, over 46 years 16.6. In Vitória, the figures were even higher. In all, 1,530 individuals were examined out of a population of 15,000 and ova were found in the faeces of 593 (38.6 per cent), doubtless more would have been found positive had more than a single examination been made. The percentages by age in this district were under 5 years 21.9, 6-10 years 45.4, 11-15 years 56.9, 16-20 years 52.9, 21-30 years 48.7, 31-45 years 30.5, over 46 years 25.0. Other helminthic infestations were common. *Ascaris lumbricoides* was found in 82 per cent of 1,151 examined, *Necator americanus* in 30 per cent of 421, and *Trichuris trichiura* in 24.3 per cent of 342. All these figures are taken from published papers and the author has a running comment on them.

According to the data investigated by the author, it has been estimated that there are nearly three million persons infested with *S. mansoni* in Brazil, but the author himself believes this to be a gross underestimate, as in the Northern States and Minas Geraes—highly endemic foci, it is true—nearly 2 million (1,817,892) have been found to be infested.

The bibliography is confined to papers published in Brazil and includes more than 350 references. [The whole work is full of interesting information and should prove useful in a few years time for gauging the results of measures undertaken to remedy the conditions now present.] H. Harold Scott

ORTELA, B. Considerações sobre a esquistosomose [*Schistosomiasis mansoni* (In Pedra Azul, Brazil)] *Brasil-Médico* 1947, Oct 4 & 11, v 61, Nos 40/41, 352-6

Infestation with *Schistosomiasis mansoni* is very common in this district. The author states that among 2,000 samples of faeces 1,280 contained the ova. From these 2,000 there should be deducted 200, as the specimens were from children under 2 years of age which were being examined for other parasites, notably *Giardia intestinalis*, and 300 others were repeat examinations. Thus, of 1,500 there were 1,280 (85.3 per cent) positive, and the author says that in certain districts careful examination, systematically carried out, would show that nearly all were infested. He gives short histories of 11 patients whose ages ranged between 5 and 70 years (the one aged 70 died) but they were all fairly typical. The treatment adopted was by tartar emetic, 1-2 per cent solution freshly prepared and diluted with hypertonic glucose for administration, starting with 0.01 gm and increasing gradually, according to the patient's tolerance, to 0.05 gm. Treatment was suspended when a total dosage of 1.0 gm was reached, and repeated after an interval of "some months". If there was

intolerance the drug foadin given intravenously was found very serviceable. Repodral [see this *Bulletin* 1947 v 44 220] says the author is excellent but needs great care in watching for toxic symptoms [but none of the patients detailed in this account was given Repodral]

SCHWETZ, J. La classification et la nomenclature des Planorbides (*Planorbinae* et *Bulininae*) de l'Afrique Centrale et surtout du Congo Belge. [Classification and Nomenclature of the Planorbidae especially in the Belgian Congo.] Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales Mémoires (Collection in-8°) 1947 v 18 No. 2, 91 pp. (31 refs.)

In this useful study of a collection of molluscs in the Museum of Belgian Congo at Tervueren, the classification and nomenclature of the Planorbidae are dealt with in a manner more lucid and refreshing to a layman than might reasonably be expected with such a difficult group. Any such contribution to the important subject of intermediaries of the Schistosomes in Africa, though in this case it has special reference to the species occurring in Belgian Congo must have special interest to medical officers in the Colonies. But the author is at pains to emphasize that although a knowledge of the correct classification is highly desirable in those who perforce or by natural interest must concern themselves with these disease carriers, the subject is a mine of pitfalls for the amateurs and that even the "experts" cannot agree with one another on certain questions of nomenclature. This is no reflection on the probity of the experts, but an illustration of the extreme complexity of the subject. He quotes J Bequaert in this connection — "The Planorbidae are a very difficult group, owing to the relatively slight differences separating the genera and species, and the great variation within specific limits. One must not expect two students to agree in every case and I admit freely that I change my own opinion from time to time."

Advice to intending investigators is contained in another quotation from Bequaert — "There are several pitfalls to guard against in the study of molluscan hosts of parasitic worms. The most outstanding is the unwarranted indictment of any fresh-water mollusk that happens to be abundant in a locality where cases of fluke infections occur. It should be fully realized that carefully controlled experiments must be forth-coming before one can incriminate a given snail as harboring the parthenetic generations of a pathogenic trematode."

"After the molluscan host is established beyond doubt its correct identification may prove an arduous task. In the absence of comprehensive works on the Mollusca of most tropical and subtropical countries it is strongly recommended to submit specimens to one of the leading malacologists. In many genera of fresh-water mollusks the distinction of species is based on characters that are difficult to describe or even to illustrate. Identification has to proceed through comparison with specimens of allied species or from several localities, which can only be undertaken in one of the larger museums."

SCHWETZ, J & DARTVILLE E. Recherches sur les mollusques de la bordure orientale du Congo et sur la bilharziose intestinale de la Plaine de Kasenyi, Lac Albert. [A Study of Molluscs on the Eastern Border of the Belgian Congo and of Intestinal Schistosomiasis in the Kasenyi Region.] Institut Royal Colonial Belge. Section des Sciences Naturelles et Médicales Mémoires (Collection in-8°) 1944, v 14 No. 2, 77 pp. 5 maps (1 folding) & 3 pls [Bibliography]

This is an account of a malacological survey along the eastern border of Belgian Congo from Lake Kivu to Lake Albert. Particular attention was given to snail collecting in the Kasenyi region on Lake Albert where intestinal

Helminthiasis

schistosomiasis is prevalent The first part of the report contains more or less detailed descriptions of localities and habitats and an account of the species of snails found therein This is followed by a systematic list of all the species collected and a discussion on their ecology and distribution In the second part, available records of the population incidence of schistosomiasis in the Kasenyi area are considered in relation to the ecology of Planorbid intermediaries The authors' conclusions are at variance with the local belief that the disease is associated with fishing, and are supported by a comparative study of the incidence in different population groups and by the fact that Planorbids are most abundant in streams and in creeks which are not fished very much

HUNTER, G W, BENNETT, H J, INGALLS, J W, Jr & GREENE, E The Molluscan Intermediate Host and Schistosomiasis japonica III Experimental Infection of *Oncomelania quadrasi*, the Molluscan Intermediate Host of *Schistosoma japonicum* *Amer J Trop Med* 1947, Sept, v 27, No 5, 597-602

Adult snails (*Oncomelania quadrasi*) were collected on Leyte from areas in which *S japonicum* infections were absent or rare, and exposed to infection with miracidia to determine (a) the number of miracidia that would produce the highest infection and survival rates in the snails, and (b) the time necessary for the production of cercariae after exposure to miracidia Information was also sought as to reproduction of snails kept in laboratory conditions

Individual exposures and mass exposures were carried out and the snails were kept under observation for 66 to 78 days, at the end of which time the numbers of surviving snails were regrettably small Individual exposures with 1 to 3 miracidia gave negative results with over 600 snails, of which only 22 survived the experimental period Exposures with 5 to 10 miracidia gave 33.3 per cent, 28.5 per cent and 16.0 per cent positives in 6, 7 and 25 snails respectively which survived from the original batch of 700 snails Mass exposures gave positives in every case in 1, 2 and 8 snails which survived from 3 batches of 909, 527 and 875 respectively There was a significant difference between the infection rates of 8.5 per cent and 62.4 per cent in snails examined before and after the 70th day, for which no satisfactory explanation is available It was thus established that the best results were obtained by exposing each snail individually to 5 to 10 miracidia and that a period of approximately eleven weeks is required for the development of the cercariae

Although the high mortality rate in the snails kept in aquaria suggests that suitable ecological conditions were not established, evidence was obtained in the form of young snails 5 months after the introduction of adult snails into the aquaria, that breeding was taking place.

PICK, F & DESCHIEUX R. La distomatose à *Watsoni* *watsoni* (Conyngha 1904) Stiles et Goldberger 1910 chez le papou. [Infection of Baboons with *Watsoni* *watsoni*.] *Bull. Soc. Path. Exot.* 1947 v 40 No. 5/8 202-11 5 figs. on 2 pls.

Infections with *Watsoni* *watsoni* have been recorded commonly among the Primates to which group they appear to be mainly confined as parasites and only one human case is definitely known that of Watson in a native of German West Africa in 1904 though Manson in 1908 described a patient with violent diarrhoea from whom many flukes were evacuated in the faeces and which were thought to be *W. watsoni*. DESCHIEUX (*Bull. Soc. Path. Exot.* 1940 v 33 306) recorded the infection in baboons (*P. pro. pharus*) for the first time and compared the clinical effects in these animals with those described in connexion with the human infection of 1904. To these data, Pick & Deschieux now add further observations on 10 baboons harbouring adult *W. watsoni*. In four of these there was chronic diarrhoea which terminated fatally and flukes numbering 200 to 1 000 were found on autopsy. The caecum was usually the most heavily infested part of the intestine. A detailed account of the post mortem findings in these four cases is provided. Of the other six cases, three had mild diarrhoea accompanied by daily evacuation of flukes over a period of two months and the condition cleared up after large masses of worms had been expelled in the course of one or two days.

Four stages in the disease are recognizable—a latent period, which may last a long time—a period of mild transitory diarrhoea of several months' duration with probable recovery—a period of serious diarrhoea of 2 to 3 weeks—a period of dehydration of a few days terminating in fatal cachexia.

The pathological lesions are characteristic and extend from the middle third of the ileum to the anal sphincter—they consist principally of inflammation of the serous membrane in the infected region of the ileum—and oedemata, congested areas and punctiform erosions of the mucosa. They are the result of mechanical and traumatic effects due to the attachment of the flukes (by the large posterior sucker) and the production of multiple stases in the circulation of the mucosa, with all the consequences of prolongation of this action. These findings contrast with those in Watson's human case in which numerous worms were found on autopsy attached to the intestinal mucosa which was lightly congested, but not ulcerated. Death had been due to diarrhoea and inanition.

Vol 45, No 4]

ARCHIVOS INTERNACIONALES DE LA HIDATIDOSIS [International
Archives of Hydatid Disease] Montevideo 1946, July, v 6, Nos 1/2, 606 pp, numerous
illustrations

This volume consists of 24 items, 16 of which deal with the literature, clinical
features, prevention and treatment of hydatid disease, and the other 8 are
concerned with the biological aspects. The last 10 pages refer to the adminis-
trative aspects of the campaign against hydatid disease. There are many and
varied illustrations, some of them in colour. The volume contains a very
great deal of information and is presented on lines similar to those of preceding
volumes [see also this *Bulletin*, 1944, v 41, 949]

MOREY SOTOMAYOR, G. Hidatidosis de la infancia [Hydatid in Children]
Rev Hosp del Niño Lima. 1947, June, v 9, No 31, 127-47, 10 figs

Much attention has been paid to hydatid in adults but its presence in the child
merits more than it has received. The author records 19 cases in the 7 years
1940-46. In 1940, there were seven between the ages of 8 and 12 years,
5 boys and 2 girls, in 5 the cyst was in the lung, in one in the liver, and in one
in liver, lung and brain. The last and one of the lung patients died. In 1941
and 1942, there was one case each year, a girl of 9 years with a pulmonary cyst
in the first, and a boy of the same age with one in the liver in the second, the
latter died. No case was seen in the next two years. In 1945, five, 3 boys and
2 girls, 3 had cysts in the liver, 2 in the lung. One, a boy aged 11 years,
with a liver cyst died. In 1946 there were again five, 3 boys and 2 girls, one,
a boy of 7 years with liver and lung cysts died but a girl of 8 years with both
liver and lung cysts recovered. The other three were a girl of 4 years and a boy
of 5 years with lung cysts, and a boy of 9 with a liver cyst, these all recovered.
To sum up. Altogether, of the 19 cases, 13 were boys, 6 were girls, there were
5 deaths, 11 had pulmonary cysts, 5 had liver cysts, 2 both liver and lung cysts,
and one had cysts in liver, lung and brain. Eosinophilia was only moderate in
any and might be lacking.

BASU S N. Chronic Intestinal Obstruction due to Ascariasis *J Indian Med*
Ass 1947 Aug v 16 No 11 390-91
Report of a case

LARA, H, GAN, T M, MATIAS, M Y & REYES, A C. *Digenia Simplex* as a
Substitute in the Treatment of Ascariasis *J Philippine Med Ass* 1946,
June, v 22, No 6, 239-42
The practical value of an anthelmintic drug depends on factors other than
its therapeutic activity, it must be available locally in large quantities.

painful nodular swellings in 4 aching joints in 3 weakness and cutaneous manifestations each in 2 and pain in the testicles, shortness of breath and pain in the abdomen each in 1 case.

In all but one case the drug produced a leucocytosis. Before treatment, the eosinophil counts ranged from 1 to 32 per cent. [actual counts not given] 24 were above 5 per cent. There was usually an increase during treatment in two cases these were over 40 per cent., in six over 30 and in 12 over 20 per cent.

At the end of 48 hours there were no microfilariae in the night bloods of 9 patients and the microfilariae were markedly reduced in numbers in the other 17. At a subsequent examination after 8 to 53 days, half the cases were shown to be free of microfilariae. In only one case was there a relatively high count, 22 microfilariae in 60 cum. after 75 days, but this patient had originally shown 339 microfilariae. This patient had received treatment for 4 days in all, but this was interrupted in the middle for a week, because of a respiratory infection. The results could not otherwise be correlated with the amount of the drug given.

The appearance in 4 cases of tender nodular swellings and of localized lymphadenitis proximal to the swellings is suggestive of the death of the adult worm. Additional confirmatory evidence is afforded by the strong eosinophilic reaction observed in all 4 and by the occurrence in 3 of them of a sharper rise of temperature which was also of longer duration than in the rest.

NOBLE, Bertha R. Informe preliminar del estudio histopatológico de dos ojos oncocercosos. [A Preliminary Histopathological Study of the Eye Changes in Onchocerciasis.] *Bol. Oficina Sanitaria Panamericana*. 1947 July v. 28 No. 7 598-606, 16 figs.

The author who is a specialist in the Onchocerciasis Section of the Pan American Sanitary Bureau, presents the results of a detailed histopathological study of two eyes—one was enucleated from a patient suffering from glaucoma, who was also infected with *Onchocerca*—the other was obtained at autopsy from a patient also suffering from onchocerciasis.

Details of technique are given and there are 16 good photomicrographs indicating lesions of the different parts of the eye examined, which included the conjunctiva, cornea, Bowman's membrane, substantia propria, iris, ciliary body, choroid, retina, optic nerve and peri-orbital tissues.

The author concludes that the microfilariae may be found in all the tissues of the eye but seem to have a predilection for the conjunctiva—no complete microfilariae could be found in the sections, but an impression was gained that they were longer than those found in the skin.

Lesions were also found in all the tissues of the eye. The inflammatory reaction was of a chronic non-specific type similar to that produced by foreign bodies.

H. J. O'D. Burke-Gaffney

TOUMANOFF, C. & LE VAN-THUNG. Note au sujet d'un cas de gnathostomose humaine observée en Indochine. [A Human Gnathostome Infection in Indochina.] *Bull. Soc. Path. Exot.* 1947 v. 40 Nos. 5/6 169-74 3 figs. [19 refs.]

The authors record and describe a case of gnathostomiasis (*G. spinigerum*) in an Annamite woman aged 42 years, from whom an immature female worm 10.5 mm. by 1 mm. was extracted.

Before its removal from a point below the left clavicle, the site of infection had been painful and slightly inflamed and later became swollen to the size

of a pea. The following day the worm was extracted (apparently by scratching the skin with a finger nail). An erythema 15 cm in diameter subsequently formed, together with an oedema which extended upward to the neck. Both disappeared in two days after local treatment and the wound healed 8 days later.

It is remarked that the skin reaction in this case differed from those described by previous authors in that the transitory oedema occurred *after* the emergence of the worm. It is suggested that in such cases the worm might escape detection by emerging unheralded, especially at night. From the case history, the infection must have been contracted either in Indochina, in which event it would be the first recorded from that country, or in Siam 16 years ago, which would indicate an extremely slow rate of development of the parasite and a very long sojourn in the human body.

J J C Buckley

TOUMANOFF, C & NGUYEN VAN HUONG. Un cas autochtone de gnathostomose humaine observé en Indochine [An Autochthonous Case of Human Gnathostome Infection seen in Indochina]. *Bull Soc Path Exot* 1947, v 40, Nos 5/6, 174-5.

Autochthonous infection with *G. spinigerum* in Indochina, strongly suggested by the case described by TOUMANOFF & LE-VAN-PHUNG [see previous abstract], is definitely established by the present authors who describe a similar infection in a Eurasian woman of 22 years who had resided all her life in Indochina. A worm, 9 mm \times 1 mm, was removed from the right lumbar region by squeezing a small irritating papule resembling a mosquito bite. Thirteen hours later, a small oedematous swelling appeared measuring about 5 cm \times 3 cm, with a central depression of about 5 mm \times 2 mm, which was surrounded by a narrow inflammatory zone. The blood count was as follows: polymorphonuclears 56 per cent, large and small mononuclears, 7 and 5 per cent respectively, lymphocytes, 20 per cent and eosinophiles, 12 per cent. This formula is similar to that observed in the previous case of Toumanoff and Le-Van-Phung. It is remarked also that in both cases the oedematous swelling had been transitory and occurred after the worm had been extracted.

YOUNG, May R. The Incidence of *Trichinella spiralis* at Necropsies in England. *J Helminthology* 1947, v 22, No 1, 49-60 [45 refs]. [Summary appears also in *Bulletin of Hygiene*].

The author examined 472 human diaphragms for *T. spiralis* infection by a "digest" technique which is described in detail.

The number examined for each town and the percentage found infected are as follows:—Birmingham, 194 (12.4), Wolverhampton 106 (15.1), Cambridge, 37 (5.4), Bristol, 48 (12.5), Cardiff, 56 (3.57), Llandough, 7 (14.3), Leeds, 24 (all negative), which give an average infection rate of 10.805 per cent.

Statistical analyses of the figures show no significant differences between the infection rates in sexes or in age groups, but an increase in the incidence of thick-cysted infections of long standing is apparent with increasing age. With the exception of Llandough and Leeds each of the towns furnished cadavers in which were found thick-walled calcified cysts, indicating an endemicity of considerable age, whilst unencysted larvae of recent infection were found in Wolverhampton and Birmingham cadavers. From the occurrence of infections of obviously different ages in one cadaver, it is argued that one infection does not produce permanent immunity.

Examination of 4,626 specimens of pork from Wolverhampton abattoir during 1941 and 1942 revealed no positives. Some of the pigs came from widely separated localities in England. Two of 145 rats from the Wolverhampton area were positive and nine of 116 from Penrith.

At the time of the Greenwich outbreak [DAVIS and ALLOTT *Bulletin of Hygiene* 1942, v 17 271] Argentine pork was suspected and 589 specimens were examined by the "digest" technique. All were negative. J J C Buckley

DAVIS, W. A. & CLELAND R. R. Trichinosis in Prisoners of War *Bull. U.S. Army Med. Dept.* 1947 Nov., v 7 No. 11 973-6.

This paper records an outbreak of trichiniasis at Camp Atterbury Indiana, during the second and succeeding weeks of December 1945. The symptoms were chiefly chills, fever, cough and generalized muscular pains and aches. Together with the "explosive onset" these symptoms suggested influenza and an epidemic of influenza type B had just occurred in Fort Benjamin Harrison camp near by but at camp Atterbury only German prisoners of war were affected, most of the patients had had mild diarrhoea at the onset of the illness, their illness lasted longer than influenza does, their muscular pains differed from those of influenza, several patients had extensive subconjunctival haemorrhages and eosinophilia was common. Practically all the Germans admitted having eaten raw pork or bacon and the diagnosis of trichiniasis was confirmed by positive skin tests in all the 20 patients thus examined.

The infection was traced to canned bacon intended for overseas shipment and to canned pork, both issued on Dec. 7 1945. The Germans had been told to cook the bacon and pork, but these products were issued to them raw and were eaten so. The epidemic became manifest 9 days after the bacon was issued. Three men suffering from trichiniasis became ill before the bacon had been issued, but they admitted having eaten raw pork earlier. By December 7 1945 103 patients had been admitted to hospital and 77 others were admitted to isolation barracks with symptoms similar to those shown by patients admitted to hospital. In addition there were 408 patients with similar but milder symptoms who were kept in their quarters. The diagnosis of these two latter groups was based on clinical symptoms only because of lack of sufficient laboratory facilities. The authors briefly discuss the prevention of trichiniasis and refer to literature most of which has been abstracted in this *Bulletin*.

VEGEMER A. FARGUEBAUM J. PIERI T. ROMAN J. DONOSO R. HORCHER, G. BENIC D. AGOSIN M. CHRISTIEY R. SOTOMAYOR D. R. SILVA C., R. & VILCHES R. Epidemia de triquinosis en la Escuela Militar de Chile. [Outbreak of Trichiniasis in a Military Training School in Chile.] *Rev. Med. Chile* 1947 Aug. v 75 No. 8 519-24 1 graph.

There were 474 students at the school and all were examined after sickness among them had been reported. Seventy-one were healthy 297 were found to be infested with *Trichinella spiralis* and 106 were "subclinical." Diagnosis was made by the high eosinophilia and positive reactions to the Bachman test. Possibly another ten were infested who were away on holiday at the time the investigation was made. The symptoms on the whole were typical but mild gastro-intestinal disturbance headache general malaise and, in some a rash, apparently petechial as it was thought at first to be typhus. Eosinophilia ranged between 0.5 and 54 per cent. The Bachman reaction was positive in 180 of the 217 in whom it was tried (82.9 per cent). Two showed electrocardiograph changes—one a simple A-V block the other anomalies of the ST segment and the T wave, pointing to myocardial damage. The source of the outbreak was traced to pork and pork sausages undercooked. The period of incubation varied between 4 and 25 days with most between 11 and 20 days.

MACANDREW MAUREN & DAVIS E. Trichinosis presenting with Foot-Drop and Facial Palsy. *J. nat. 1915 Jun. 21 141*

SPRUE

WREY, F. Outbreaks of Sprue during the Burma Campaign. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1947, Dec., v. 41 No. 3 377-406. [23 refs.]

A number of papers have appeared on the unusual aspects of sprue in outbreaks among British and Indian troops in Burma. They all deal more or less with cases of the same type and with a similar environment. The subject matter bears the same flavour of perplexity: all the various observers pursue their individual methods of approach though their conclusions appear equally mystifying and inconclusive. Such a one is the present contribution. It therefore covers much the same ground but the author would explain the epidemic nature of the outbreak on dietary grounds which others for their own good reasons would discard. This contribution in particular is long and detailed and therefore does not lend itself to concise summary.

The author observed a large number of military patients—over 3 000—and describes the incipient manifestations of what is usually a particularly chronic disease. It is not surprising, therefore, that all stages of severity were encountered, but it may justifiably be concluded that the syndrome here described was indeed tropical sprue in all its various stages of development, as is borne out by the therapeutic response to liver treatment and other recognized measures. The primary aetiological factor was believed to have been a dietary deficiency of certain components of the vitamin B₂ complex, and in this respect the author finds himself in variance with others.

The majority suffered from a mild form of the disease, conforming to the recently described 'para sprue' and the author advances cogent reasons against the acceptance of what is after all a spurious division and emphasizes that there is no fundamental difference between European and Indian cases. The most noteworthy variants were the watery, more frequent, less bulky stools and lower fat content, as compared with the typical sprue evacuations seen in peace time. For this the relatively short duration of the disease, the amount and nature of fatty acids and carbohydrates, the intestinal hurry and deficiency of calcium were regarded as important. The large putrescent stool of the fully developed disease is probably the outward sign of megacolon, and is therefore a later development. Not all cases showed the same pattern. The commonest features were lethargy, muscular weakness, anorexia, flatulent dyspepsia, white diarrhoea, glossitis, anaemia and emaciation.

But even in the early stages, there were abundant evidences of abnormal fat excretion. The primary causal factors were thought to be prolonged consumption of a diet inadequate in one or more components of the vitamin B₂ complex. It is claimed that there was a calculable deficiency of riboflavin, nicotinic acid and pyridoxine. This was borne out, in the author's opinion, by the excretion of subnormal amounts of nicotinic acid and the therapeutic response to parenteral and oral administration of crude liver extract and other vitamin B₂ complex preparations.

It is stated that troops subsisting on rations richer in fresh foods did not contract sprue.

[In this respect the K rations come in for some criticism. It is not stated that deficiency symptoms *per se* were due to vitamin deficiencies in these rations but that they were so monotonous that they were not eaten. The error lay in the

assumption that men could subsist on them over indefinite periods. Bacillary dysentery was rife in these jungle-fighters and approximately 10 per cent. of them developed sprue symptoms in addition for which the primary bacillary infection was held responsible.]

Secondary aetiological factors were the increased metabolic demands made by the arduous of this exhausting campaign, increased by malaria, dysentery antecedent malnutrition and anaemia, and consequent anorexia. The high carbohydrate intake in Indian cases and the excessive fats in British cases were subsidiary causes. The author's final conclusion is in support of the Stannus hypothesis (this *Bulletin* 1943 v 40 259) that sprue is primarily the expression of failure of phosphorylation of glucose and fatty acids through lack of co-enzymes which act as catalysts. These include certain unspecified fractions of the vitamin B₁₂ complex.

There was no evidence that the development of sprue was dependent on an infective agent antecedent intestinal disease or inherent metabolic error.

That these outbreaks of sprue occurred in epidemic proportions is not considered a cogent argument against the diagnosis of sprue or as supporting the hypothesis of its infective nature.

HAEMATOLOGY

MACFARLANE R. G. & O'BRIEN J. R. P. in collaboration with C. G. DOUGLAS, E. M. JOYE, H. M. JOYE, R. H. MOLE, B. AMOS & P. GURLOCK. The Haldane Haemoglobinometer. I. Iron, Oxygen and the British Standards Institution Colour Standard. *Brit Med J* 1944 Feb. 19 448-50

Samples of heparinized venous blood from 29 men and 20 women in normal health were used in an investigation of the efficiency of the Haldane-Gowers haemoglobinometer. The following determinations were made on each blood sample: oxygen capacity by the constant volume van Slyke method; haemoglobin iron determination by the Klumpff titanous chloride method; ultra-violet and visible absorption spectra; haemoglobin estimation with the Haldane-Gowers haemoglobinometer. British Standard Institutions (B.S.I.) standards, diluting tubes and pipettes being used; red cell count and packed cell volume. It appeared that the 100 per cent. on the B.S.I. standard Haldane-Gowers haemoglobinometer was equivalent to about 19.7 ml. oxygen per 100 ml. and to about 49 mgm. of haemoglobin iron per 100 ml. instead of the expected 18.5 ml. oxygen per 100 ml. and 48.25 mgm. iron. It also seemed that there was a sex factor in the different proportions of iron, oxygen and colour found. Further the iron content and oxygen capacity were not strictly proportional to the readings obtained with the Haldane haemoglobinometer and the spectrophotometer. Part of the discrepancy was due to instrumental and technical difficulties while part may have been due to the presence of inactive haemoglobin or non-haemoglobin iron the presence of which in larger amounts in men than in women might account for the observed sex difference. It seems

reading between 2 and 6 per cent. lower than that given by the method of van Slyke. Secondly in matching the diluted haemolysed blood against the standard in the Haldane instrument, it is very important to observe the simple precautions laid down by Haldane himself. Before discarding the Haldane haemoglobinometer for clinical use, careful consideration should be given to its many advantages. The modern carboxyhaemoglobin standards can be accurately calibrated both at the time of manufacture and subsequently during use, and they remain stable for several years. The glassware can also be calibrated accurately and any needed correction applied. In contrast to photo-electric methods, the Haldane method is little affected by slight turbidities in the final solution and unusual haemoglobin derivatives such as methaemoglobin after sulphonamide therapy can often be detected by their tint.

F Margetroyd

GOODALL, J W D GOODALL, Hilda I. & BANNERJEE D Folic Acid in Nutritional Anaemia. *Lancet*. 1948, Jan. 3 20-21

Ten cases of nutritional anaemia were studied in Calcutta. The criterion was severe anaemia which did not correspond to the pure iron-deficiency type these cases represented examples of dimorphic anaemia. Four were undoubtedly nutritional macrocytic anaemia after childbirth the patients were so weak that they were unable to stand. Their red cell counts were about 500 000 per cmm. and haemoglobin was in the neighbourhood of 2 gm. per 100 ml. They were of the type where blood transfusion is contraindicated, but since the introduction of folic acid there have been no fatalities. One patient in particular did not respond to liver and iron for 15 days but within five days from the commencement of folic acid, progressive improvement was registered.

Megaloblasts were present in the bone marrow in seven out of the ten cases. It is concluded that folic acid in 10 mgm. doses twice daily gives a rapid haematological response in nutritional macrocytic anaemia and an equally rapid improvement is noted in the diarrhoea, fever and oedema which is often present in these cases. Furthermore it is effective whether the bone marrow is normo- or megaloblastic and is superior to liver extract in these cases. It is specially recommended as a simple remedy in the nutritional anaemia of women after childbirth.

P Manow-Baker

WAGLEY P F Neurologic Disturbances with Folic Acid Therapy *New England J of Med* 1948 Jan. 1 v 238, No. 1 11 15

In this paper the author suggests some limitations of the therapeutic value of folic acid. He studied 14 cases of macrocytic anaemia, comprising 10 cases of pernicious anaemia, one of tropical sprue, 2 of non-tropical sprue and one of macrocytic anaemia after total gastrectomy. Nine cases are discussed in detail. The response to folic acid was excellent in the single case of tropical sprue and one of the two cases of non-tropical sprue and no neurological disturbances developed in these three cases.

Neurological disturbances developed or recurred in 8 of the 10 cases of pernicious anaemia. In 3 of the 10 cases glossitis either developed or was unresponsive to folic acid. The response in the patient who developed macrocytic anaemia after total gastrectomy was slow but improvement did occur the treatment was changed to liver therapy in the later stages.

The author suggests that his observations indicate that, with our present knowledge, the use of folic acid entails definite risk of injury to the nervous system in pernicious anaemia.

VENOMS AND ANTIVENENES

CHRISTENSEN, P A **Formol Detoxication of Cape Cobra (*Naja flava*) Venom.**
South African J Med Sci 1947, June, v 12, No 2, 71-5

Cape Cobra venom loses toxicity, combining power and nitrogen when exposed to the action of formalin. The rate of loss of toxicity increases with increasing formalin concentration and increasing pH, and the loss is due partly to formation of toxoid and partly to destruction.

Some loss of antigenicity accompanies loss of toxicity and combining power may be completely lost after the prolonged action of formalin. Martin's broth, *per se*, is not necessary for detoxification, its action is that of a buffer and if the reaction of saline solutions of venom is adjusted to pH 7, toxoid formation proceeds normally and yields a superior product. Optimal conditions are low concentration of formalin and low pH, and under these conditions the tendency for the formation of undesirable precipitates of low antigenic value is reduced.

DERMATOLOGY AND FUNGUS DISEASES

O'BRIEN, J P **A Study of Miliaria Rubra, Tropical Anhidrosis and Anhidrotic Asthenia** *Brit J Dermat & Syph* 1947 Apr-May, v 59, Nos 4/5, 125-58, 26 pls (1 with 2 coloured sketches) & 1 text fig

As the author points out, few common tropical diseases have received less attention than miliaria rubra. This article embodies the results of two years' research embracing the clinical, histological and experimental aspects of miliaria rubra, tropical anhidrosis and anhidrotic asthenia, the subject being an

Australian soldier The author suggests that miliaria rubra and tropical anhidrosis represent the acute and chronic phases of sweat gland occlusion, while anhidrotic asthenia is a general metabolic disorder resulting from wide spread occlusion of sweat glands and consequent reduction in total sweat production.

Although on superficial inspection the skin appears normal as soon as the symptoms of miliaria have passed away every affected gland does, in fact, remain chronically obstructed for a long time afterwards. Close inspection of the skin involved shows keratin plugs discernible as multiple minute greyish, shining macules. After the patient has undergone severe physical effort close scrutiny reveals deep vesicles implanted within the skin these vesicles can be seen to disappear after the person affected has rested in a cool place. With the starch-iodine technique it may be demonstrated that each of these vesicles indicates the site of an obstructed sweat duct. If anhydrous lanoline is smeared on an area of unclothed anhidrotic skin, and the subject exercised, profuse secretion of sweat occurs on this area while the rest of the skin remains completely anhidrotic. This is clearly illustrated in a photograph.

When a large portion of the covered parts is rendered sweatless, and the subject attempts physical effort in heat, anhidrotic asthenia results. This is characterized by symptoms of exhaustion, transient amnesia, vertigo frontal headache, dyspnoea palpitation and the sensation of heat. The author considers that some impairment of tropical adaptation results from blockage of half a person's sweat glands, and where two-thirds or more are blocked the loss of adaptation may be severe. After some experience, examination of all affected persons immediately after exercise will allow precise immediate assessment of the degree of tropical adaptation in each individual case.

The histological changes of sweat gland occlusion are illustrated by thirty-four plates, in which four stages are illustrated. Stage I shows the closure of the sweat pore as a result of the swelling and closure of the keratin ring at its mouth. Stage II shows the primary rupture of the sweat duct and the formation of the miliarial vesicle as a result of pressure built up within the obstructed sweat gland. Stage III shows the formation of a keratin plug at the site of the obliterated vesicle and Stage IV, the secondary rupture of the sweat duct and the formation of the deeper vesicle of tropical anhidrosis.

The suggestion is made that sebaceous deficiency in the tropics causes a physical change in the keratin ring surrounding the sweat duct, with resultant occlusion and rupture of the duct. In the presence of lipid the keratin lamellae are softened, the ring becomes pervious again and sweating occurs. This is the author's interpretation of the result of the experiment in which sweating occurs after lanoline has been smeared on the anhidrotic skin. Treatment is therefore aimed at desquamation of the stratum corneum with 10 per cent. salicylic acid in 90 per cent. alcohol, followed by inunctions of lanoline to restore the lipid deficiency.

[This is a most interesting article based on a very detailed study of miliaria rubra and its effects. The author advances an ingenious suggestion for the mechanism of its causation.]

VARELA, G & AVILA, C "Mal del Pinto" or "Carate" and its Treatment with Chlorhydrate of 3-Amino-4 Oxiarsenbenzen (Mapharsen) *Amer J Trop Med* 1947, Nov, v 27 No 6, 663-72, 4 figs & 1 map [42 refs]

There are said to be 700 000 cases of pinta in the Americas, of which 270,000 are in Mexico. The causal organism *Treponema caratatum* was discovered in 1938. It develops abundant growth "in cultures of nervous tissues of mouse embryos" (simplified technique of Dr Pomerat, Medical School of University of Texas [no details or reference given]). There is said to be no immunity to reinfection during the disease or after recovery, nor to infection with syphilis. Yaws patients are claimed to be partially immune.

The author, working at Arcelia, Mexico, found 56 per cent of children of parents infected with pinta were themselves infected, while only 43 per cent of those having parents free from pinta were affected. The coloured, red, pink, blue, brown and white, lesions, or pintides, are more numerous on the exposed surfaces of the body and shoulders. Palpitations occurred in 40 per cent (of 200 patients) and the blood pressure tended to be low. Other authors have reported aortic lesions in pinta and also a high incidence of positive Wassermann and Kahn reactions which did not respond very readily to treatment. No changes have been found in the cerebro-spinal fluid.

The authors gave 0.04 grammes of "Mepharsen" twice weekly to men and women for a maximum of 15 doses. Of 66 cases observed for periods up to one year, in only three had the intensity of the Kahn reaction decreased and in 60 there was some improvement in the coloured areas. C J Hackett

TROPICAL ULCER

PINKERTON J M Tropical Ulcer, as seen in South Iran, and its Treatment with Penicillin *J Trop Med & Hyg* 1947, Dec, v 50, No 12, 243-51, 8 figs

Tropical ulcer is very prevalent in South Iran, causing much invalidism and a certain number of deaths, it is usually associated with under-nourishment and bad hygienic conditions.

The author divides his cases into two main types—Type I "simple tropical ulcer" and Type II "phagedaenic" tropical ulcer. A few cases are classified as "transitional" or as "atypical".

Type I ulcers are irregularly circular, with a rolled edge or reddish-purple colour and a base of paler exuberant granulations exuding thin sero-pus. These ulcers seldom exceed 4 or 5 inches in diameter and are usually on the lower extremity, most often in the region of the tendo Achillis or external malleolus. Cases of this type invariably show Vincent's bacilli and spirochaetes, often associated with staphylococci and sometimes with other organisms. There is

often a marked resemblance to rodent ulcer and the author excised some of his earlier cases for this reason. This type is seasonal in its incidence and occurs during the first autumn rains in November after the long hot summer—it is more common after a poor harvest.

Type II is believed to develop from Type I by infection with anaerobic gas-producing organisms although bacteriological proof of this has not been obtained. The ulcer enlarges its base becomes deeply excavated, lined by wash-leather or dark green or black sloughs, and the discharge becomes copious and foul-smelling. Spreading gangrene occurs involving fascial planes, tendons and structures with a poor blood supply. Toxaemia begins with intermittent fever and progressive anaemia, the ulcer may enlarge to an enormous size even encircling the whole limb and before the advent of penicillin amputation offered the only hope although even then gangrene was liable to occur in the stump. The bacteriology of Type II does not differ much from that of Type I. Type II hardly ever attacks the young and vigorous. There are a few ulcers of an atypical kind, often on the upper limb which are common in Europeans.

Nine cases treated with penicillin are described. The first was a case of atypical tropical ulcer 1 inch by $\frac{1}{2}$ inch, on the middle finger of an American cook, which had followed upon a septic wound and had remained stationary for two weeks in spite of various forms of treatment. Wassermann and Kahn reactions were negative and Leishman-Donovan bodies and *Trep. pallidum* were not found. Penicillin was given by intramuscular injection in doses of 20 000 units every 4 hours omitting one dose (100 000 units in the 24 hours). This was continued for three days (300 000 units in all) and on the fourth day the ulcer was healed. The remaining cases were all in Iranians.

Case 2. Typical Type I. Ulcer four inches in diameter above the external malleolus. Wassermann and Kahn reactions negative. Penicillin, 100 000 units daily was given intramuscularly for five days with marked effect. The area, now clean was covered with a Thiersch graft which was 90 per cent. successful and three weeks later the whole ulcer was healed.

Case 3. Typical Type II. The patient had been under various treatments for 3 months with no improvement. Wassermann and Kahn were negative. Anaerobic cultures were made with negative result. The patient was very toxic and had a large foul-smelling ulcer in the popliteal region. Penicillin was given intramuscularly 100 000 units daily for five days with striking immediate effect. Within a week the condition relapsed and thorough debridement together with opening up a sinus extended to the buttock was performed, and penicillin 100 000 units daily for five days was again given. The wound was packed with saline gauze and the limb put in plaster twelve days later the plaster was removed and ten days after this Thiersch grafts were applied. These were only partly successful but healing was complete within a month, penicillin cream being applied locally.

Cases 4 5 6. These were Type I ulcers in young men in good condition. All received 400 000 units of penicillin in four days and recovery was rapid. Skin-grafts were applied in all, with complete success, and the patients left hospital completely healed within a month.

Case 7. This was an ulcer in the popliteal space, classed as of transitional type although the patient was already showing signs of toxaemia. 500 000 units of penicillin produced rapid improvement in the general and local condition. Skin grafting was delayed for treatment of a heavy *Bact. coli* infection, but the patient left hospital after three months with the ulcer healed.

Case 8 was transitional. A sloughing tendo Achillis was seen in upper part of the ulcer. A tentative attempt to pull out the slough without an anaesthetic failed, and 500,000 units of penicillin were given. Temporary

improvement occurred but when the drug was stopped, the ulcer began to spread again. No further supply of penicillin was available at the time and a month later the ulcer had enlarged considerably and the whole length of the slough had been removed, together with over half the tendon. A second course of 400,000 units of penicillin was given and skin grafting was possible within a week. The ulcer had healed after four months' treatment.

Case 9 Type II ulcer A man aged 50 had been under treatment for two and a half months with progressive enlargement of the ulcer which was of enormous extent—10 by 8 inches—over the dorsum of the foot. The patient was wasted and very toxic with intermittent pyrexia. After the superficial sloughs had been removed, he was given two courses of penicillin, separated by a short interval and totalling 1,600,000 units, with dramatic effect. This case, however, proved very obstinate owing to a heavy secondary infection with *Ps. pyocyanea* and *Bact. coli*, and developed a generalized eczema, believed to be an allergic reaction to penicillin cream. The ulcer was healed in a little less than four months after commencement of treatment with penicillin.

In his summary the author observes that "Type II" ulcers, before the advent of penicillin, almost invariably caused death unless amputation was performed; that Vincent's bacilli and spirochaetes are met with in all types and disappear after penicillin treatment; penicillin proved to be specific for all types of tropical ulcer, in "transitional" and Type II ulcers, thorough débridement is an essential preliminary to penicillin treatment, and the only ill-effect of penicillin treatment was a severe allergic skin reaction in one case [See also this *Bulletin*, 1948, v 45, 209] C F Shelton

MISCELLANEOUS DISEASES

DAVIES, J N P **Pathology of Central African Natives** Mulago Hospital Post Mortem Studies IV *East African Med J* 1947, Oct, v 24, No 10, 352-62 [24 refs] [Summary appears also in *Bulletin of Hygiene*]

This paper continues the author's previous records [this *Bulletin*, 1948, v 45, 211] and deals with tuberculosis in Africans. He begins by referring to various differences in the type of infection and the course of the disease in Africans as compared with Europeans. Although it is generally agreed that the disease as met with in Central and East Africa is of a severe and acute type, no instances have been found of the very malignant form described in 1920 in Senegalese who had been transported to France and which followed on a primary tuberculous ulceration of the trachea and bronchi. WILCOCKS in East Africa [*Bulletin of Hygiene*, 1938, v 13, 628] found active pulmonary tuberculosis to be common and fibrotic reactions relatively uncommon. This has been the experience of many other workers.

The author divides his cases seen in Kampala into two groups (1) Those autopsied from May 1931 to May 1946, and (2) those autopsied in 1946, there being an overlap of 25 cases. The reason for this separation is that in 1946 closer observation has been made in certain aspects of the disease.

In group (1), out of 2,994 autopsies, evidence of tuberculosis was found in 11.8 per cent, and in group (2) out of 460 cases, in 18 per cent. The apparent increase in incidence was not a true one, but the result of greater interest being shown in the disease, as many fatal cases as possible were examined.

In group (1), of 354 cases of tuberculosis 86.8 per cent were pulmonary and 13.2 per cent non-pulmonary, while in group (2) the figures were 88.7 and 11.3 per cent respectively. Bone and joint affections were rare, but a high proportion showed glandular involvement.

The evidence found post-mortem suggested that in Uganda the disease is rarely of the adult "reinfection" type but is usually the result of a primary infection with formation of a Ghon focus which fails to heal and leads to dissemination. In many instances, the lungs are riddled with acute tuberculous abscesses (a condition described by the author as "pantuberculosis"). In those cases where it was possible to determine the initial focus (about a fifth to a quarter) this was in the lower lobe but in many cases this focus could not be found. The pulmonary lesions were of a very acute type, fibrotic phthisis was very rare and the picture was one of a purulent infection without cavitation but with ragged thin-walled abscesses, the sputum teeming with tubercle bacilli. Laryngeal and tracheal lesions were frequent and the same applied to tuberculous ulceration of the intestines, while military dissemination and giant cell formation were common.

In 1946, the duration of the illness was noted in 35 cases and found to average 7.7 months. Only 6 children were autopsied, the average age of 286 adults examined was 29.5 years. No cases of healed phthisis were found, but 5 chronic cases were noted. Adrenal tuberculosis was seen in one case only and renal tuberculosis was uncommon, surgical tuberculosis while met with in the wards, was not often found at autopsy. Tuberculous peritonitis was common and the incidence of myocardial tuberculosis relatively high. A striking lesion was a general glandular form of tuberculosis, this being found in 15 cases. Every lymphatic system in the body may be involved, and in some cases there may be a close resemblance to Hodgkin's disease.

It would appear that in Uganda the great majority of cases are of the human type of infection [see CARSTEN, *Bulletin of Hygiene* 1939 v 14 215]. Tuberculin testing has not been carried out to any great extent in Uganda, but it may be noted that Connolly in 1941 in the Nyanza Province of Kenya obtained 28 per cent. of positives at ages 13-17 and up to 53 per cent. positives in adults. He contrasts these results with the absence of cases of tuberculosis and thinks that under conditions in the reserves the African can deal with this infection. In Uganda it appears from post-mortem findings that tuberculosis is usually "primitive" tuberculosis, and the anatomical evidence tends to show that most Uganda Africans never have the chance of being infected. When this does occur a very few develop a primary complex which they can overcome, the remainder when they do meet infection (usually by inhalation) develop a massive primary infection which may be situated anywhere in the lungs, dissemination taking place through the glands, the blood stream or by bronchopneumonic spread. The whole process tends to be rapid and death occurs without any attempt at localization. This is the clinical interpretation as well and there is no evidence of anything but a primary complex being healed.

MATTHEW R. L. Creeping Eruption caused by the Larvae of the Cattle Hookworm *Bunostomum phlebotomum*. *Proc. Soc. Exper. Biol. & Med.* 1947 Oct. v 68 No. 1 12-14 1 fig.

While engaged in inoculating the skin of calves with third stage larvae of *Bunostomum phlebotomum* the cattle hookworm the author on a number of occasions noted the appearance of small inflamed spots between his fingers. Some of these increased to about $\frac{1}{2}$ inch in diameter in a few hours and 2-3 days later a narrow linear tortuous eruption appeared, this extended at intervals for a few days. Later a raised vesicular line usually developed within a few hours. It might be interrupted in some places. The affected area became swollen and intensely itchy especially in the mornings. The condition usually cleared up with a scaly skin, in about a fortnight.

A typical lesion acquired in this way in 1946 is described in detail, with daily records of its development. This occurred on the interdigital surface of the ring finger and is illustrated in a photograph. Areas where hair follicles were present were not affected, so that there was no evidence that the larvae penetrated by way of these follicles.

Evidence is also given to show that, in man and calf alike, a prickling sensation was produced almost immediately after the application of the larval suspension to the skin.

The lesions correspond closely with those seen in creeping eruption caused by the larvae of the dog hookworm, *Ancylostoma brasiliense*, but in the case of the cattle hookworm, the duration of the lesion is less prolonged. In the author's experience it lasts from 1 to 3 weeks, while that caused by the dog hookworm lasts from several weeks to months.

It is also suggested that the cattle hookworm larvae do not penetrate in such large numbers. Secondary infection sometimes develops in creeping eruption, as a result of continued scratching, but no such complication was noted by the author in the case of the present lesions. It is also noted that the eruption caused by the cattle hookworm has much in common with schistosome dermatitis, but there is no migration in the latter condition.

ROSS, S G. Preliminary Report on Fish Poisoning at Fanning Island (Central Pacific). *Med J Australia* 1947, Nov 22, v 2, No 21, 617-21

The author gives an account of 55 cases of fish poisoning under his personal observation between February 1946 and the first week of April 1947. Forty other cases were reported to him during this period, making 95 in all out of a population of 224.

The symptoms were the same as those recorded previously from the Marianas and Honolulu and may be briefly summarized here [they have been described more fully in this *Bulletin*, 1945, v 42, 592, 593, 1946, v 43, 595]. The indigenous people cook the whole fish on burning coconut husks after wrapping it in green leaves mostly pandanus or palm tree leaves, Europeans clean the fish and cook the flesh only. Symptoms of poisoning occur after either form of preparation for eating and the poison is in the fresh fish. In one instance recorded, the fish, a snapper, was caught at 3 p.m., cleaned at once and put on ice, fried at 4 p.m. and eaten an hour later by 8 persons. All were taken ill 4-5 hours after with gastro-intestinal disturbances followed by numbness and tingling in face and limbs, a sensation of intense cold when hands or feet were immersed in water at room temperature, or in the mouth on attempting to drink. The pulse was slow, 35-40 per minute and pupils contracted [reaction to light or convergence is not mentioned]. The gastro-intestinal symptoms soon cleared off, but the nervous symptoms did not disappear for a week or more and a general weakness might persist for several weeks. No fatal case is reported, but the author states that the clinical symptoms generally are becoming more severe and the nervous features more marked. So far, ten species of fish have given rise to these symptoms, the popular and local names are stated, but not the scientific names. Those mentioned are Rock cod (grey and red), Blackjack, Bonefish, Reef fish, Snapper, Greenfish, Mullet, Red Snapper and Bream. The first the Reef fish and the last-named are non migratory, the others migratory. All except the Blackjack

ENTOMOLOGY AND INSECTICIDES GENERAL

- l. MARKS Elizabeth N. Studies of Queensland Mosquitoes. Part I. The *Aedes* (Finlayae) kochi Group with Descriptions of New Species from Queensland, Bougainville and Fiji. *Univ. of Queensland Papers Dept. of Biology* 1947 July 9 v 2, No. 5 68 pp., 20 figs. [34 refs.]
- d. — Studies of Queensland Mosquitoes. Part II. New Species of *Aedes* (Subgenus Finlayae) *Ibid.* July 9 v 2, No. 6, 10 pp. 3 figs.

1. In 1943 the Government of Queensland established a National Mosquito Control Committee a function of which was to institute a research programme dealing with all aspects of the mosquito problem in Queensland. This paper is the first of a series concerned with the systematics and biology of these mosquitoes.

Aedes (Finlayae) kochi is an efficient vector of *Wuchereria bancrofti* and several species have been confused with it. The object of the first paper is to clear up some of this confusion and it contains descriptions of the males of *A. kochi* and *A. wallacei* and of both sexes of four new species (*A. bougainvillensis*, *fijensis*, *alocasicola* and *gahusicola*). There are also descriptions of the larvae of all the foregoing species and of *Aedes solomonis* and of the pupae of all except *wallacei* and *fijensis*. There are also notes on other species and keys for the identification of adults and larvae of this group. Important morphological details are figured.

ii. Two new species are described in this paper *Aedes* (Finlayae) *candidoscintellum* and *Aedes* (Finlayae) *rosselli*.

LORD K. A. & JOHNSON C. G. The Production of Dermatitis by Pyrethrum and Attempts to produce a Non-Irritant Extract. Reprinted from *Brit. J. Dermal & Syph.* 1947 Nov v 59 367-75.

Extracts of pyrethrum applied to the skin form one of the most effective repellents for mosquitoes and other insects. Unfortunately these extracts contain substances to which many people become sensitized after repeated applications and then an erythema or an intensely itching papular rash is produced. Among groups of 62 men and 27 women who applied a gum tragacanth cream containing a commercial extract of pyrethrum behind the ear each day for 4 to 10 weeks, 9.7 per cent. of the men and 45.9 per cent. of the women became sensitized. (The authors point out that the higher incidence in women is not statistically significant.) When sensitization developed it was general applications to the skin elsewhere produced a reaction. The factor responsible for the dermatitis does not appear to be pyrethrin itself. If pyrethrum extracts in petroleum ether are percolated through a column of fuller's earth, the dermatitis factor is more strongly adsorbed than the pyrethrins and a preparation with less of the responsible factor can be obtained. But no extracts were prepared wholly free of the sensitizing substance. I B Wigglesworth

YATES, W W & GJULLIN, C M **Pre-Hatching Applications of DDT Larvicides on Floodwater *Aedes* Mosquitoes** *Mosquito News* 1947, Mar, v 7, No 1, 4-6

Extensive areas bordering the Columbia River, U S A (46 N 120 W) are flooded by the seasonal rise of the river and are the site of extensive breeding of *Aedes vexans* (Meig) and *Aedes lateralis* (Meig). Plots in these areas were sprayed with a DDT emulsion (prepared by dilution with seven parts of water from stock containing 25 per cent DDT, 68 per cent xylene and 7 per cent Triton X-100) before flooding was expected. Subsequently larvae failed to reach maturity over these treated areas and the authors found by experiment that an application of 3 pounds of DDT per acre will leave a residue in the soil nine months later, which is toxic to newly-hatched larvae, despite interim flooding on two occasions

INCHO, H H & DEONIER, C C **Comparative Toxicity of DDT to Three Representative Species of Mosquito Larvae** *Mosquito News* 1947, June, v 7, No 2, 67-70

Laboratory tests of the toxicity of DDT preparations to three species of mosquito gave the following results (taken from tables) —

| DDT preparation | Concentration (p p m) of DDT to give 86 to 96 per cent kill in 24 to 48 hours of | | |
|----------------------------|--|--|----------------------|
| | <i>Culex quinque-fasciatus</i> [fatigans] | <i>Anopheles quadrimaculatus</i> | <i>Aedes aegypti</i> |
| 1 Stable suspension | 0.25 | 0.05 | 0.025 |
| 2. Stable emulsion | 0.25 | 0.05 | 0.017 |
| 3 Acetone-water suspension | 0.25 | 0.05 | 0.025 |
| 4 DDT in fuel oil | 0.5* | 0.05* | 0.025* |
| | | [60 to 66.8 per cent at 0.025 lb per acre] | |

* lb per acre

It was observed that with preparations which spread equally through the body of the water, *Culex* was much more resistant than *Anopheles* or *Aedes*. This must reflect a specific toxic effect. The *Anopheles* was also susceptible to preparations confined to the surface (oil solution and also dusts) but the *Aedes* was protected by its feeding habit and therefore apparently resistant.

HADAWAY, A & BARLOW, F **Toxicity of DDT applied to Limewash** *Bull Entom Res* 1947, Dec, v 38, Pt 3, 489-95

Glass plates were painted with limewash (of stated composition) and subsequently sprayed with DDT solutions or emulsions. Tests were also done with pieces of limewashed plaster from houses. The insecticidal effects were determined by exposing tsetse flies (*G. palpalis*) or mosquitoes (*Aedes aegypti* or *Anopheles gambiae*) to the treated surfaces for short periods, and observing the mortality twenty-four (occasionally forty-eight) hours later.

It was found that very low mortalities followed exposure to limewash treated with DDT as compared with glass surfaces similarly treated. This was not due

to chemical decomposition of the DDT for the insecticide could be recovered and identified afterwards. Also it was shown that the amount adsorbed on the lime was negligible. The loss of toxicity is due to a simple masking effect owing to the particles of inert solid covering the DDT. A similar effect occurs with DDT emulsion, but not with a DDT dispersible powder which remains on the surface of the limewash. With the last mentioned formulation, however there is a certain masking effect on a clean glass surface because of the inert diluents already present in the dispersible powder. (The one tested contained only 5 per cent. DDT.)

A few tests with a water paint containing DDT gave analogous results. Toxicity was low because of masking of the DDT which was buried in the paint. An increase of the thickness of the paint layer naturally enough, made no difference to the insecticidal effect.

BUSHLAND R. C. Comparative Tests with DDT and Phenothiazine against two American and Three New Guinea Species of Mosquito Larvae. *Mosquito News*. 1947 Mar. v 7 No. 1 14-17

Laboratory tests were done in Florida and in New Guinea in 1944 and 1945 with various species of mosquito larvae. The insecticides were added in acetone solution to large beakers and very fine (clear) suspensions were produced, to which the larvae were added.

The DDT was lethal at rates from one in 20 million to one in 150 million, for the different species. Towards *Culex quinquefasciatus* [fatigans] *Anopheles walkeri* and *Aedes aegypti* the DDT was about fifty times as toxic as phenothiazine [thiodiphenylamine]. Towards *Anopheles punctulatus* DDT was seventy times, and to *Culex annulirostris* DDT was 150 times, as toxic as the phenothiazine.

YOUNG E. G. Stability of Aerosol Formulations. *Soap*. New York. 1947 Nov. v 23 No. 11 116-17 152A.

In order to prevent decomposition of aerosols in metal containers it is desirable to add a small quantity of a compound which inhibits corrosion of the metal. This paper reports tests of various substances for the purpose. They were added to a normal aerosol (containing DDT and pyrethrins) and stored at 67°C. for several months with a strip of metal from the aerosol bomb container. It was found that 0.001 to 0.1 per cent. of propylene oxide, salicylal, amino guanidine or certain other compounds very greatly reduced corrosion and decomposition of the aerosol liquid. At these rates the additives were negligible in their effects on the insecticidal functions of the aerosol.

FAY R. W. COLL E. L. & BURRIS, A. J. Comparative Residual Effectiveness of Organic Insecticides against House Flies and Malaria Mosquitoes. *J. Econom. Entom.* 1947 Oct. v 40 No. 5 635-40 3 figs.

Some new insecticides were tested for residual contact action against *Anopheles quadrimaculatus* and *Musca domestica* with exposure of 15 to 60 minutes in small treated cages of plywood (3x3x12 inches). Mortality was determined after twenty-four hours in a clean cage. All substances (except pyrethrins) were tested at 100 or 200 mgm. per square foot. The order of effectiveness at the end of twenty-six weeks was (1) DDT (2) Benzene hexachloride (30 per cent. gamma) (3) Chlordane (4) Toxaphene and (5) DDD [Dichloro diphenyl-dichloroethane]. The pyrethrins (at 10 and 1 mgm. per sq. ft.) with addition of piperonyl cyclohexane or piperonyl butoxide had very little residual

effect The relative toxicity of the different insecticides was the same for houseflies as for mosquitoes, but while loss of toxicity was abrupt with the former, it was gradual with the latter

The effectiveness of a selection of commercial DDT wettable powders varied considerably, though all were applied at the same rate J R Busvine

OKULOV, W [The Results of the Examination of the New Soviet Insecticidal Preparation, Pentachlorine Paste *Med Parasit & Parasitic Dis* Moscow 1947, v 16, No 1, 33-5 [In Russian]

The author reports promising results of tests carried out under laboratory conditions with a new Soviet insecticide "pentachlorine paste", which contains 40 per cent DDT A 10 per cent aqueous emulsion of the paste was sprayed on various objects, 10 mgm of pentachlorine per 1 cub m of surface was used On drying, the treated surfaces showed no trace of the substance applied A narrow glass ring was then attached to the treated surface Within it were placed the insects, and the ring was covered with a glass plate After a certain period of time, the insects were removed into a test tube and observations were made on their behaviour These tests were carried out with sandflies, mosquitoes, flies and bugs Sandflies and flies proved to be the most susceptible to the action of the preparation, contact during 5 minutes being sufficient to destroy them within 5-8 hours In the case of mosquitoes, contact for 50-55 minutes was required to kill them after 30-31 hours Bugs required longer contact, after which they perished in 8-15 hours The duration of contact and the interval before death increased when the insects were exposed to surfaces which had been sprayed from 10 to 45 days previously The advantages of the new insecticide are its prolonged effect upon insects, the absence of any traces of its use on the treated surface, its complete innocuousness for animals and human beings, and the small amounts required for use in dwellings [There does not appear to be anything new in the principle, which is an adaptation of DDT]

CRANDALL, B S Removal and Prevention of Fungus Stain of Photographic Negatives in the Tropics *J Biol Phot Ass* 1947, Dec, v 16, No 2, 78-80

In the tropics, photographic negatives, stored in boxes or open drawers, may rapidly deteriorate by becoming covered with fungus mycelium The problem can be solved for 35 mm film negatives by storing them with silica gel in tins which can be hermetically sealed For larger negatives this method is impracticable In the Amazon region, it was found that immersion in the standard fixing bath "hypo" for five to ten minutes cleared the stain from the negative, and that the solution acted as a fungicide Negatives so treated remained free from fresh infection for four months Negatives have been protected from

fungus infection for ten months by immersing them in a 1 in 1 000 solution of mercuric chloride immediately after washing, or in a solution of "Lignosan" containing 2-4 gm. per litre.

[Lignosan is ethyl mercuric chloride.]

REPORTS SURVEYS AND MISCELLANEOUS PAPERS

MANSION-BAHR, P. *The Practice of Tropical Medicine in London. Trans. Roy. Soc. Trop. Med. & Hyg.* 1947 Dec. v 41 No. 3 289-94 1 chart 2 diagrams & 4 figs. on 1 pl.

The Presidential Address at the opening of a Session of the Royal Society of Tropical Medicine and Hygiene offers scope for a wide variety of reflections on diseases of warm climates, or for a summing up of personal experience. In the latest of these addresses, Sir Philip Manson-Bahr has chosen the latter course, and presents a series of observations on tropical diseases as he has seen them during more than a quarter of a century of practice in London. His emphasis throughout is on the unusual, the atypical, and on the need for thorough examination of each patient and for judgment when the seemingly obvious diagnosis is not quite right. The address is, in fact, an account of a series of diagnostic puzzles—it was given with the verve and liveliness characteristic of the author's speeches.

It would not be possible to abstract this paper satisfactorily and the reader is advised to study the original, and then perhaps to ponder on the possible missed diagnoses of his own experience: the tumour of the left kidney mistaken for a spleen, the high remittent temperature due to unsuspected ischio-rectal abscess, the rectal carcinoma which is in fact an amoeboma, the cholecystitis which turns out to be sprue.

The impression left upon one member of the audience is that medical men in Britain, called upon to treat patients from the tropics, should be particularly careful not to overlook tropical diseases in differential diagnosis, and also that those accustomed to look for tropical diseases should not overlook non-tropical conditions. Medicine is difficult enough in temperate climates, but tropical conditions make it more so—yet if there were no difficulty there would be no skill or need for knowledge and judgment. Sir Philip Manson-Bahr begins his paper by referring to the supreme importance of judgment. Judgment, no doubt is a gift but it can be cultivated, and it is evident that to improve it the doctor must learn from his own experience and to do this must follow up his cases.

Charles Wilcocks

MANSION-BAHR, P. *The Manson Tradition. J. Trop. Med. & Hyg.* 1947 Dec. v 50 No. 12, 233-43. [13 refs.]

The Manson tradition needs no bush—but as continuity is the essence of history it requires constant renewal for each generation if its freshness is to be maintained.

To restate the tradition of the Father of Tropical Medicine no one is better equipped, in status and in qualifications alike, than Sir Philip Manson-Bahr himself for he is as closely linked to that tradition as the tradition is linked to him.

In this paper Sir Philip recapitulates some of the outstanding features of Manson's life, achievements and outlook, and illustrates them with vivid personal memories which strikingly reveal the greatness of the man and of his work.

Stress is laid on his broad approach to scientific problems ' though sometimes unorthodox according to modern conceptions, "in his hands they proved, as results have shown, to be eminently successful" Indeed, history has shown that many now classical achievements by others in the field of tropical medicine had their origins and background in Manson's hypotheses and in his "prophetic instinct"

Manson was a clinician who saw the paramount importance of preserving the clinical aspect of medicine, whatever other specialized forms it might take and he trained himself, when no others existed to train him, in those specialized fields He was, above all, a teacher but he was "no hidebound doctrinaire His outlook was broad he was well versed in literature and possessed more than superficial acquaintance with other branches of science and natural history"

Passing from Manson himself to the wider fields which he had laid open, the author corrects any impression that the wells of tropical research have been exhausted during the last six years alone, the opportunities given to many eager workers in wartime have borne great fruit examples are given of new additions to our knowledge of tropical medicine, epidemic polyarthritis, epidemic thrombo-phlebitis, kwashiorkor, tropical eosinophilia and cardiology in the tropics are mentioned, much new light has been thrown on the transmission and control of insect-borne disease, treatment and prevention have been enriched by modern methods, technique and drugs, and, especially, many preconceived theories of the physiology and pathology of well-known diseases, for example blackwater fever, malaria, cholera and heat-stroke, have been shown to be untenable

The author concludes by showing how tropical medicine, despite its great gains in wartime, has itself suffered from the ravages of war, and he enters a plea for the preservation and reconstruction of materials and means of teaching on the same high standard hitherto maintained A suggestion is put forward for the foundation of some form of organized association—the name "the Manson Association" is suggested—which would preserve the Manson tradition, voice its own views and opinions, knit more closely in fellowship those teaching and working in tropical medicine and perhaps institute a regular Manson lecture Such an organization might also institute a central pool for building up a depository of pathological specimens and other material

If the prestige of British Tropical Medicine is to be preserved in a changing world, its devotees require to be bound more closely in their common task, and for this purpose there could be no greater or more appropriate central figure around which to rally than that of the Father of Tropical Medicine himself

HAMBURG Tätigkeit und Aufgaben des Hamburger Tropeninstituts [Activities and Aims of the Tropical Institute, Hamburg] 36 pp 1947

The Institut für Schiffs- und Tropen-Hygiene, now the Tropical Institute, Hamburg, was founded by Bernhard Nocht in 1900, with the following objectives in view (1) The treatment of exotic infective diseases and diseases of warm climates (2) Research on a wide basis in tropical medicine and hygiene (3) Education and instruction of doctors students, laboratory workers and others in tropical diseases, parasitology and epidemiology

In the latter years of the late war, much of Hamburg was devastated by bombs and by fire and the Institute suffered severely but it is rising, phoenix-like, from its ashes and this booklet explains what has been done for renewing its work It embraces the following sections Clinical (under Professor Nauck) helminthological (Professor Reichenow in charge), entomological (Dr Weyer), chemical (Dr Kessler), bacteriological (Dr Lippelt) pathological and virus

research (Professor Nauck) veterinary (Dr Enligk) epidemiology (Professor Nauck). In addition there is an animal house for the usual small laboratory animals—mice, guinea-pigs, rats, rabbits, birds, cats and dogs—and later there will be accommodation for larger animals, horses, pigs, sheep, etc.

Courses of lectures are given by the various heads of departments in their different specialities. The books of the library though removed to the basement in the war were mostly destroyed by bombs and by fire, but attempts are being made to replace lost books and papers. Finally there is to be, as of old, a museum for demonstration of photographs and specimens.

The booklet gives the titles of 31 papers published from the Institute since 1945 of 25 more at present in the press and 18 in preparation. [It will take a long time and will be a difficult uphill task to bring the new Institute to the standard of the old which as older workers in tropical medicine will remember was one of the finest in the world.]

BOOK REVIEW

MARTINI E. *Lehrbuch der medizinischen Entomologie*. [Textbook of Medical Entomology] 3rd Edition. pp. xvi+633 322 figs. 1946. Jena Verlag von Gustav Fischer [Rm. 29]

The first edition of Professor Martini's textbook on medical entomology was published in 1923 [see this *Bulletin* 1923 v 20 768] the second edition in 1941 and the present volume in 1946. The third edition follows a plan similar to that of the first edition (the reviewer has failed to obtain a copy of the second edition) and maintains the same high standard as a guide to those interested in the part played by arthropods in causing disease in men and animals. That a book of so considerable a size—there are about 600 closely printed pages—is no more than a guide to medical entomology is the outcome of the author's inclusion of accounts of arthropods of mainly and often solely veterinary importance the space available for the title subject is further reduced, by descriptions of the morphology and life-cycle of the parasites carried by the vectors not only during their development in the invertebrate host but also during their sojourn in the vertebrate. Professor Martini stresses in his preface the difficulties under which he laboured while writing this third edition and it is significant of these difficulties rather than a reflection on the author that he makes but little reference to important recent advances in our knowledge of medical entomology. This lack of modernity is illustrated by an examination of the bibliography where out of nearly 1,000 references the reviewer has encountered only forty-one thirty-nine of which are in German concerning papers published after 1939.

The paper used in making this book is of exceptionally fine quality and does full justice to the many excellent illustrations. The price Rm. 29 appears more than reasonable indeed, it is doubtful whether at the present time an equally well produced volume could be published in Britain at a similarly low price.

TROPICAL DISEASES BULLETIN

[No 5

1948

Vol 45]

CHLORINATION AND VIABILITY OF *Entamoeba histolytica* CYSTS
By T C St C MORTON, OBE, MD, FRCP, DTM & H, KHP
Air Commodore Royal Air Force
R A F Institute of Pathology and Tropical Medicine

Interest in the prevention and cure of amoebiasis was stimulated after the 1914-18 and 1939-45 world wars alike. The only real advance in treatment during the recent war was the introduction of penicillin and sulphaguanidine to counteract the secondary bacterial infection of the gut. Control of the disease has not received adequate attention, probably because of the divergent views of recognized authorities on the mode of transmission. Some emphasize the rôle of water-borne infection and others stress the direct contamination of food and drink by cyst carriers. However, it is agreed that flies play an important secondary rôle as vectors between fresh human faeces and food, but the degree of importance must vary with the humidity because the higher the humidity, the greater the viability of the cysts.

ANDREWS (1934) has shown that in volunteers who scraped their fingers through faeces containing cysts, the maximum viability of the cysts was 45 minutes in those with long finger nails, and only 15 minutes in those with short. If this fact is confirmed, the food handler is only likely to remain infective for about an hour after defaecation. The routine use of soap, water and a nailbrush could reduce the time still further, and indeed completely neutralize this source of infection.

Sources of Infection

Fresh fruit and salads which are eaten uncooked, such as grapes, lettuces, radishes etc., have deservedly acquired an evil reputation as sources of infection. Unfortunately, the time-honoured measures advocated to render them "safe" to eat savour more of a magical rite than an effective hygienic measure. Potassium permanganate achieved its reputation as a panacea because it was effective in killing the cholera vibrio in a dilution of 1/500,000 in fifteen minutes (NAPIER 1945), but even a 1 per cent. solution of potassium permanganate is not effective against the cysts of *E. histolytica* after twenty-four hours' immersion (CRAIG, 1944). Recent work indicates that after thorough washing to rid the fruit or vegetables of gross organic matter, immersion in a strong solution of bleach for half an hour should render them reasonably safe.

Viability of *Entamoeba histolytica* Cysts

Survival—The length of survival of cysts is a subject of fundamental importance from the public health point of view, but it was only when cultural methods were introduced that a reliable method of testing for viability became

available. YORKE and ADAMS (1928) found that cysts in faeces always perished at room temperature within nine days. Washed cysts, in concentrated preparations in water survived for seventeen days at 0°C. and for ten days at 18-20°C. CHANG and FAIR (1940) found that cysts survived in water for ninety days at 32°F but only for 3 days at 86°F. STONE (quoted by CHANG, 1944) states that cysts from cultures were still viable after fourteen months at 32°F.

Thermal Death Point.—YORKE and ADAMS (1928) using the culture viability test found that the thermal death point was 50°C. (122°F). Cysts survived for thirty minutes at 45°C. but under similar conditions were killed in five minutes at 50°C. CHANG (1944) recommends immersion of fruit and lettuce, obtained from unsafe sources, for thirty seconds in boiling water. After being treated in this manner the fruits or vegetables may be freshened by placing them in the ice-box or by immersion in ice-cold boiled water.

Chlorination.—In 1917 WENTON and O'CONNOR stated that cysts of *E. histolytica* could resist free chlorine in water to a strength of 1/10 000 for some hours. Eosin staining was used as the criterion of death, but the fallacy of such a standard was demonstrated by CHANG (1940) who showed that cysts were found to be non-viable by the culture method even when 40-70 per cent. of them failed to take the stain. In 1944 Chang demonstrated further that even when cysts were kept at between 40° and 50°C. for four to five months after death between 30 and 40 per cent. of them failed to be stained with eosin. He postulated that while the nuclei of the cysts were no longer viable, the cyst wall might resist the infusion of dye for a long time. YORKE and ADAMS (1928) by means of cultural methods, found that cysts were killed in thirty minutes in water containing free chlorine in a strength of about 100 parts per million at laboratory temperatures of between 20° and 25°C. They found that with 21 parts per million of free chlorine under the same conditions, scanty cysts survived. LIU (1928) also using culture methods, stated that with 5 000 parts per million of free chlorine a contact period of six hours was required to kill all the cysts. SPECTOR, BAYLIS and GULLAN (1934) using eosin staining as a criterion of death, found that cysts were not all killed by an initial dose of chlorine of 500 parts per million in a contact period of 48 hours. These authors also stated that chlorine was more effective than chloramines in killing cysts. GARCIA (1935) based his conclusions on the improved assumption that cysts showing disappearance of nuclei or broken nuclei and disappearance of karyosomes were dead, and that those showing only distortion

of nuclei and disappearance of karyosomes were alive. On this basis he stated that cysts in a thick fresh faecal suspension were killed in 1½ hours with an initial dose of chlorine of 3.5 parts per million while 3 500 parts per million of free chlorine were required to kill the washed cysts in the same contact period. (In the author's case a dilution of CaOCl_2 of 1/100 000 expressed as chlorine was equal to 3.5 parts per million, the available chlorine present being 35 per cent.) He concluded that the killing power of chlorine is tremendously increased in the presence of large amounts of organic material, when chloramines are formed. STONE (1937) on the other hand reported that cysts of *E. histolytica* were not more resistant than *Bact. coli* to chlorine in tap water. He found that in tap water with a density of 1.975 cysts per cc. and a total organic nitrogen content of 45 parts per million, an initial dose of 4 parts per million of free chlorine killed all cysts and *Bact. coli* in twenty minutes. When the total organic nitrogen was increased to 101.25 parts per million, 10 parts per million of free chlorine were required. Cyst suspensions from washed cultures were used, and for tests of viability both eosin staining and culture methods were employed. BRADY JONES and NEWTON (1943) using raw surface water to which 20 cysts per cmm. were added, found that with an initial dose

Chlorination and Viability of Cysts

of 2.73 parts per million of free chlorine, cysts were still viable at the end of thirty minutes, but by multiplying the dose 2 to 10 times, only 8 cultures were positive out of 640. Of 150 cultures exposed for over 15 minutes to fifteen times the dose, none was positive for *E. histolytica*. In the positive cultures obtained after exposures of twenty minutes or more to concentrations of 2.73 to 9.83 parts per million of chlorine, the frequency of positives was haphazard and bore no relation to the amount of the dose of applied chlorine, nor to the duration of the exposure. A possible explanation for this phenomenon is that a few cysts were protected from the action of the chlorine by particles of organic matter which exerted a dechlorinating effect in small localized areas, such a phenomenon was observed by REGAN (1942) in the case of *Bact. coli* in polluted tidal waters. If such circumstance is of common occurrence, occasional survival of a few cysts may be expected under field conditions unless the water is filtered before chlorination.

CHANG and FAIR (1941), using cysts from cultures and testing viability by cultural methods, evaluated the cysticidal effect of chlorine in terms of temperature, density of cysts and pH. They found that the higher the temperature, the lower the pH value and the longer the contact period, the greater the cysticidal effect. Doubling the density of the cysts necessitated the use of a 25 per cent higher concentration of chlorine.

CHANG (1944) with a concentration of 40 washed cysts per cc and working with gaseous chlorine, an aqueous solution of chlorine, and with chloramines, carried out a very elaborate series of experiments in which the strengths of the stock solutions and of the residual chlorine were determined by the acid-starch iodide method. The pH of the chlorinated water was estimated by an electrometer and in the expectation that the oxidation-reduction potentials of the chlorinated water might show a close relation between the concentration of chlorine and the cysticidal efficiency, the voltage of the chlorinated water was determined by a brilliant platinum electrode against calomel half cell. All experiments were carried out at 18°C and nitrogenous organic matter from domestic sewage and from proteose peptone was used in varying amounts in a parallel series of experiments. In addition, studies were made to find out whether there was a penetration of chlorine into the cysts and what sort of morphological changes took place in them after chlorination. He found that with a high concentration of chlorine, such as 50 parts per million, 65-75 per cent of the cysts were stained yellow with orthotolidine, and that these yellow-stained forms were coarsely granular. He found that the cysticidal activity of solutions of chlorine, or of chloramines, is associated with the entrance of free chlorine into the cysts. The coarsely granular appearance of cysts was thought to indicate that chlorine probably combined with the proteins in the protoplasm and rendered the latter insoluble. However, in most of the tests made, the cysts were usually killed long before the chlorine was detectable in them, and before the gross changes in appearance had taken place. In several tests it was found that the death of cysts was associated with morphological changes of the nuclei. The earliest changes were splitting of the karyosome and irregularity of the nuclear membrane followed by irregular granules of the karyosome and a broken or disintegrating nuclear membrane. The most advanced stage was a total disappearance of the nuclei with irregular granules scattered in the cyst. It was apparent that the death of a cyst was brought about by the destruction of the nuclei, the first sign of which might be the splitting of the karyosome. This, according to CHANG, showed that the criterion for viable and non-viable cysts which GARCIA (1935) had postulated on the basis of the morphological changes seen after chlorination, was not justified. The viability of chlorinated cysts was determined by culture methods. The cysts in each bottle were recovered by centrifugation and were placed in a

tube of liver infusion agar medium which had already been seeded with the bacterial flora isolated from a culture of the N.R.S. strain of *E. histolytica*. Chang suggests that the death of a cyst is the result of the destruction of its nucleus by chlorine—that the destruction of nucleus depends on the penetration of the chlorine into the cyst—that the penetration of chlorine into the cyst depends on the nature of the chlorine compound—and that the amount of active or free chlorine in the water depends on the hydrogen ion concentration of, and the amount of organic matter and ammonia present in, the water and also on the temperature of the water. The oxidation-reduction potential seems to give a more accurate measurement of the cysticidal or germicidal efficiency of chlorine, since it indicates the amount of active or "free" chlorine present under all conditions.

Chang found that, at a pH of 7 and a temperature of 18°C. gaseous chlorine applied for 15–30 minutes is the most powerful cysticidal agent hypochlorite is slightly less so and chloramine the least. For long contact periods, such as 120 minutes the efficiency of all three was about the same.

In another series of experiments he showed that with a pH of 7 at a temperature of 18°C. and with a total organic nitrogen content of 0.1 to 0.19 parts per million, an initial free chlorine of 3 parts per million was effective on raising the pH to 8.5 11 parts per million were required to kill all cysts in 30 minutes' exposure.

Summary

The results obtained by different investigators are divergent and contradictory. On critical examination it is obvious that this divergence is due to two factors: different criteria for assessing the viability of the cysts after treatment with chlorine—and the different conditions, chemical, physical and biological (such as the density of cyst suspensions) under which the tests were made.

(a) *Viability*.—The early workers used eosin staining as a criterion of the death of cysts. Chang and Fair (1941) showed this method to be very unreliable. Cysts were found to be non-viable by culture, although 40–70 per cent. failed to take the stain—cysts were kept at 40°–50°F. for four to five months after the period of viability as shown by culture and some 30 to 40 per cent. failed to be stained by eosin. The authors concluded that, while the nuclei of the cysts were no longer viable the cyst wall may resist staining by eosin for a long time. Similarly the morphological appearance of cysts after chlorination cannot be entirely relied upon as an index of viability. Culture methods, provided adequate controls are used, remain the only practical criterion for viability.

(b) *Varying conditions under which the experiments were performed*.—Much of the work of the early investigators is vitiated by the facts that few of them defined the conditions under which these tests were made and that they did not take into account the importance of the temperature, hydrogen ion concentration, density of cyst suspensions and amount of organic matter present in the water.

Conclusions

Under ideal conditions as little as four parts per million of free chlorine will destroy the cysts of *Entamoeba histolytica* in water after thirty minutes. The presence of organic matter and its varying nature under field conditions, preclude sole dependence on the cysticidal properties of chlorination. This is taken into account in the sterilisation of water in the service water carts, where both filtration and chlorination are carried out.

Potassium permanganate, as a means of sterilizing fresh fruit, lettuces, etc. should be abandoned and replaced by strong solutions of bleaching powder containing at least 100–200 parts of free chlorine per million. Subsequent washing should then be done with safe water.

A level teaspoonful of good bleaching powder added to a gallon of water makes approximately a strength of 100 parts per million of free chlorine

SUMMARY OF RECENT ABSTRACTS*

IV TRYPANOSOMIASIS

AFRICAN TRYPANOSOMIASIS

Actiology

FAIRBAIRN and BURTT (p 506) have studied the infectivity to man of a strain of *Trypanosoma rhodesiense* isolated in 1934 by CORSON and maintained by cyclical transmission through *Glossina morsitans*, mainly in sheep and antelopes. It is still highly infective to man and shows no sign of reverting to a *T. brucei* type. The authors have noted the fact that a fly may fail to infect a volunteer at one bite, but succeed later, or that the volunteer may be infected by one fly, but not by another, both infected from the same source. They think that the explanation of these anomalies lies in the dose of metacyclic trypanosomes ejected by the fly, and after counting trypanosomes ejected by flies attempting to feed, conclude that the minimum infecting dose for this strain is about 350 trypanosomes. The power of a strain to invade the salivary glands, and its virulence, are also factors, and the authors discuss these. Virulence and infectivity to man are separate and independent, variable qualities. The authors discuss the changes in infectivity to man that may be brought about by prolonged residence in sheep, and changes in virulence which are probably the result of mutation of genes. In comment, Corson suggests that the authors' views on the size of an infective dose may not be accepted unreservedly by some workers, and that there may be a factor of selection working on a heterogeneous strain.

In a long and closely reasoned paper, FAIRBAIRN and CULWICK (p 649) set out their views on the electrical charges of trypanosomes and the effect of these charges (positive and negative in different individual trypanosomes) on

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947 v 44. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

attraction to or repulsion from other trypanosomes or red blood cells, themselves charged. The authors describe long short and intermediate forms, and report observations which indicate that syngamy occurs, trypanosomes with opposite electrical charges fusing and later dividing. This process results in a heterogeneous population. BLOOM adds a comment to his abstract of this paper—the whole subject should be studied in the original.

The same authors (p. 1051) show that a sub-strain of *T. rhodesiense* maintained by cyclical passage through tsetse and sheep remained polymorphic for 12 years, whereas another substrain, maintained (in England) by syringe passage through mice has become monomorphic. They argue that it is known that syringe-transmitted strains of the *brucei* group tend to become more sensitive to arsenicals, and that any chemotherapeutic tests should be carried out on strains which are polymorphic and which have been and are, transmitted by *Glossina*.

LEWIS and LARGRIDGE (p. 980) have studied the trypanosomes (*T. brucei*) ejected by tsetse flies from time to time after infection, and describe the course of development which these appearances suggest that the trypanosomes undergo in the flies. Details should be sought in the original.

WEINMAN (p. 1051) describes a new medium of agar and human citrated plasma and red cells, for the cultivation of *T. gambiense* and *T. rhodesiense*.

Transmission

SCHWITZ (p. 508) discusses the distribution of species of *Glossina* in West Africa—he thinks that this is not wholly regulated by climate and vegetation.

BIGGART (p. 294) describes the tsetse flies of Liberia. There are 4 known species of which only one *G. palpalis* is a vector of human trypanosomes. He advises on measures to control these flies by recognized methods. FARRERA (p. 1052) contributes a note on the biology of *G. palpalis* in Portuguese Guinea, which is a confirmation of work done elsewhere.

JACKSON (p. 47) allowed *G. morsitans* to hatch from pupae in part of Tanganyika Territory in which this species does not occur and studied the flies subsequently caught. Most of these were males, and most of them had fed by the fourth day. There is good correlation between age and fraying of the wings. The average distance from the point of hatching at which the flies were caught was nearly 400 yards in the first week to nearly 1 000 yards in the fourth though some were found more than 1 000 yards away. Second generation flies were found, showing that mating had taken place. BOKIT (p. 803) has previously shown that *G. morsitans* hatched from pupae incubated at 30°C. are more effective vectors than those from pupae kept at laboratory temperature but he now notes that this laboratory temperature, in East Africa, may reach 30°C at certain times of the year. The difference is that incubated pupae remain at that temperature, whereas the others reach it only from time to time.

GLASGOW (p. 47) has observed the seasonal abundance of biting flies in Tanganyika Territory but concludes that none of them is satisfactory as an indicator species to point the way to an understanding of tsetse distribution and activity.

THOMPSON (p. 803) reports a nematode of the *Merms* type in tsetse flies.

Control Treatment Prophylaxis

Three Annual Reports (for 1944-46) of the Sleeping Sickness Service of Nigeria have been reviewed (McLATCHIE p. 971). The staff of this Service was reduced to a maintenance basis during the war but survey and re-survey work was continued, and protective clearing work was done on a considerable scale, so that by 1944 about 400 000 people had been protected by communal effort. Work on the Anchan tsetse free corridor was continued, on the lines of development of agricultural resources. In the mining areas, examinations of labourers

are made every 6 weeks, and the average incidence each 6 weeks was 0.67 per cent in 1945, high enough, but much lower than in 1940. The highest rates of infection found in re-surveys in 1946 ranged from 2 to 12 per cent in individual hamlets in Katsina, with an average of 2.8 per cent. In most parts of this province the figures show very great reduction over those of 1936-37. Trials of pentamidine as a prophylactic are continued, and a report is given on the trial of certain other drugs in treatment.

MORRIS (p. 51) has attempted control of *G. palpalis* and *G. tachinoides* in the Northern Territories of the Gold Coast by protective and eradication clearing. Protective clearing, for example where a road crosses a stream, entails total clearing along the water-course, a total clearing for one mile reduces fly by about 90 per cent. Eradicative clearing entails permanent removal of those species of trees and bushes which give shelter to the flies, especially in the dry season. He begins at the head waters of a river system, and eliminates these trees from the whole system, working down-stream. In one area having 250 miles of river, he achieved by this method an almost (but not quite) total elimination of fly, and a great reduction in sleeping sickness and cattle trypanosomiasis, and thus opened the land to re-settlement.

VANDERPLANK (p. 804) has shown that DDT is lethal to all species of *Glossina* but that when it is applied to cattle, or to screens, its effect is greatly reduced within a few days because the crystals are brushed off by vegetation or washed away by rain. In tests with mosquitoes and tsetse flies, BARLOW and HADAWAY (p. 1053) have found that DDT and gamma benzene hexachloride are absorbed into leaves to the extent of 20-50 per cent, that on mud walls aqueous suspensions leave more effective films than solutions or emulsions, and that limewash interferes with insecticidal action, largely by physical absorption or masking of the particles. A "sticker" (sulphite lye) also masks the activity of DDT, presumably by coating the particles.

FINDLAY *et al.* (p. 406) have found some repellent action for tsetse flies in four substances, which they name

VEATCH (p. 293) reports on surveys made in West Liberia in 1941-43, when 90,980 persons were examined and 13,481 cases diagnosed, and again in 1943 in N.W. Liberia, where 32,617 persons were examined, and 2.2 per cent found infected. Much of the second area had been surveyed in the first expedition. Men were affected more often than women, and the common age incidence was 20-40 years. Only 6 per cent showed infection of the nervous system. Details of treatment with antrypol and tryparsamide are given. Good results were achieved.

VAN HOOFF (p. 1048) describes the trypanosomiasis campaigns in the Belgian Congo, where each year between 2 million and 5 million people are examined, and infected persons treated. The proportion of infected has remained constant for 10 years at about 0.25 per cent, and there are general reports of an increase in cases resistant to arsenicals in some places reaching 50 per cent. The recent trend has therefore been to give more attention to prophylactic injections of pentamidine, which protects for 6 months. Arsenic-resistance probably exists in most mixed strains of *T. gambiense* and the resistant strains are selected and eventually predominate as a result of mass treatment with arsenicals. But resistant strains are not so easily transmitted as normal strains by flies [see also PÉLISSIER below]. The author thinks that malarsen oxide is useful for the treatment of patients with resistant strains (a conclusion not shared by LOURIE). Dogs, pigs and goats can be infected with *T. gambiense*, and may play some part as reservoir hosts in nature. The author failed to infect man with *T. brucei* by the bite of infected flies. He found that immunity to *T. gambiense* is of short duration in animals cured of the infection, but that there

is evidence of cross immunity between *T. gambiense*, *T. rhodesiense* and *T. brucei* but not between these and *T. congolense*.

Owing to the difficulty of completing the usual course of 12 injections of trypanamide, at intervals of one week, in patients with *T. gambiense* infection in the Gold Coast, FOWLER (p. 978) has given intensive courses of 2 gm. each day for 6-9 days, either by intravenous drip (lasting 8 hours for each injection) or by ordinary intravenous injections. The results, in a small series of patients, were reasonably good.

PALLISER (p. 975) discusses trypanamide in the second stage of *T. gambiense* sleeping sickness, in relation to dosage and to the question of arsenic-resistance. During the war supplies of trypanamide were limited, and it was therefore decided that the course should be reduced to 8 injections. The results, as determined by re-survey some four years later, were not good, and a course of 8 doses is consistently less effective than one of 12. Moreover it has been found that trypanamide is less effective now than it was in the early days of its use, probably owing to the development of arsenic-resistant strains: there is a tendency to stabilization of results because the arsenic-resistant strains are not so easily transmitted by *Glossina* as the ordinary strains. He also discusses the toxic action of trypanamide and the Jarisch-Herxheimer reaction, and the question of arsenic resistance of the patient. ERRANTIS (p. 49) gives evidence which suggests that in one area of the Belgian Congo where trypanosyl had chiefly been used, there had been a considerable development of arsenic resistance. This was later countered by a method of detecting arsenic-resistant strains and treating them with antrypol, tartar emetic and trypanamide but the method was difficult. He used antrypol as a prophylactic in the uninfected population, and is enthusiastic as to its value. It apparently cleared an endemic focus.

CROCCALDI (p. 45) gives an account of the activities of the Pasteur Institute of Brazzaville in relation to sleeping sickness during 1944. Cases were discovered by mobile units and at fixed dispensaries. Trials were made of *p*-arsenosophenylbutyric acid in treatment, but the results in general, were not favourable when compared with those achieved by the older remedies. WILLIAMSON and LOURIE (p. 48) have shown that this compound acts on trypanosomes, even if resistant to trypanamide but that if *p*-aminobenzoic acid is given before the arsenosophenylbutyric acid, the action of the latter is inhibited, probably because the PABA limits its admission into or on to the trypanosome cell. WEINMAN (p. 295) reports on two trivalent arsenical preparations in sleeping sickness in Liberia, namely melarsen oxide and *p*-arsenosophenylbutyric acid. Only a few patients were treated with these drugs.

SCHUELLER *et al.* (p. 1052) have used the method of determining the extent to which mapharsen inhibits the utilisation of glucose as *in vitro* by trypanosomes, as a measure of the anti-trypanosome effect of that drug and have used strains of *T. equiperdum* of different degrees of arsenic-resistance.

PIERREON (p. 885) claims success in trypanosomiasis by treatment with silver arsenate, but does not give details of the type of infection, or the dosage used.

LEVADITI and VAISMAN (p. 186) confirm old work that fresh rabbit liver extract renders atoxyl trypanocidal *in vitro* and that glutathione and cysteine have the same effect.

SCHNITZER *et al.* (p. 185) have investigated the rôle of antibodies in the development of drug-resistance by *Trypanosoma equiperdum*. The paper is technical and the subject is complicated: details should be sought in the original.

DE BORGGRAVE (p. 570) shows that the quinoline derivative Chinoxal can *in vitro* sterilise blood infected with *T. gambiense* and that it can be used in

blood transfusion work where there is a possibility that the donor is infected. It shows little activity as a therapeutic agent.

VAN HOOFF *et al* (p 979) have shown that the protection against *T gambiense* conferred on guinea-pigs by injection of pentamidine is not increased by repeated injections of cultures of the trypanosome at intervals after the drug injection, and is therefore presumably independent of specific immunization. They consider that, in proper dosage, this drug may protect man for a period of 6 months, whereas Bayer 205 is said to be active for only 3 months, and is more toxic. They have used pentamidine on a large scale for this purpose, in a dose of 5 mgm per kilo. CLAESSENS (p 49) has used propamidine isethionate by intramuscular injection of 5 mgm per kilo of body weight, as a prophylactic in the Belgian Congo. Of 131 people so injected, one was found to be newly infected within 6 months. LAUNOY and LAGODSKY (p 702) find a correlation between the size of protective dose of pentamidine (below toxic level) and the period of protection conferred in rats against subsequent infection with *T brucei* and other trypanosomes.

Clinical Findings

LAPEYSSONNIE and LAPEYSSONNIE (p 295) report a case in which trypanosomes [presumably *T gambiense*] were found in ascitic fluid. In comment, BURKE-GAFFNEY records a similar case seen in East Africa [where the trypanosome was probably *T rhodesiense*].

HENDERSON-BEGG (p 509) has found heterophile antibodies in the serum in trypanosomiasis, although in some respects these differ from those found in infectious mononucleosis, care should be taken in diagnosing the latter disease in Africa, on the strength of this test.

COOKSON (p 975) states that in both trypanosomiasis and leishmaniasis there is excess of serum globulin and euglobulin, and that this can easily be detected by the serum-formalin test. He has used this on sleeping sickness patients and suspects, and although positive results are given in some other conditions, he regards it as a useful ancillary in diagnosis.

Trypanosomiasis of Animals

FULTON and LOURIE (p 403) have studied immunity in mice infected with *T congolense* and *T rhodesiense*, and subsequently treated with phenanthridinium or diamidine compounds. Homologous immunity was marked, with complete failure to reinfect after 20 to 26 weeks respectively, but the immunity sometimes broke down, and this may have been due to changes in the antigenic structure of the trypanosomes as they are passaged. *T congolense* is antigenically more labile than *T rhodesiense*, and lability renders the immunization of animals, or man, difficult in the field, where there are many antigenic types.

DAUZIER (p 805) discusses the immunity associated with drug treatment of certain experimental trypanosome infections. The original paper is a long thesis and an adequate summary is impossible in a small space.

A study of plasma proteins, erythrocyte sedimentation rate, potassium levels in serum and blood, and fragility of red cells during the course of infection with *T brucei*, *T equiperdum* and *T lewisi* in rats, is reported by IKEJIANI (p 572), but for details the reader should consult the original.

LAWS (p 804) find that the method of counting *T congolense* against leucocytes, in thick films, gives a reasonably accurate measure of the infection in cattle. LAUNOY and PRIEUR (p 509) show that the two phenanthridinium compounds S 897 and S 1553 are active against *T congolense*, and can be injected subcutaneously.

VAISMAN (p 981) reports experiments which indicate that, under certain conditions of infection, *Trep duttoni* attenuates infection by *Trypanosoma brucei* and *T equiperdum* in mice.

CHAGAS'S DISEASE

TORREALBA (p. 187) has republished a series of his own papers on Chagas's disease in Venezuela most of these have already been reviewed, but together they form an extensive survey of information. SEIJAS RIVAS (p. 297) reports on Chagas's disease in part of Venezuela.

POYCE CARALLERO (p. 54) found a few cases of Chagas's disease in Bolivia, and remarks that the presence of *T. cruzi* in the blood is transient. ALCAL TORRESO (p. 510) names 35 vertebrate hosts of *T. cruzi* and the 7 commonly infected bugs of Bolivia.

ROMANA *et al.* (p. 404) found 23 per cent. of children in one area of Argentina, positive to Chagas's disease by xeno-diagnosis, and 51 per cent. by complement fixation test.

D'AKDURAIN (p. 511) found infection in the rodent *Octodon degus degus* in Chile.

FLOCK (p. 53) in French Guiana infected *Rhodnius pictipes*, *R. prolixus* and *T. rubrofasciata* with *T. cruzi*, the two first more readily than the last. There is evidence that the local strains are more specially adapted to them than to *T. rubrofasciata*.

HARKING (p. 1054) has cultivated *T. cruzi* in tissue cultures of rat embryo cells. Leishmania forms appear in cardiac muscle cells, and eventually complete trypomastotes are formed which become extra-cellular.

ADLER and BICHOWSKY (p. 52) have found that biotin concentrate inhibits the growth of *T. cruzi* and certain other protozoa, but the active substance is the concentrate is not biotin itself.

MUNIZ and DE FREITAS (p. 296) have found that if *T. cruzi* is washed free of all blood constituents before being inoculated into the liquid of fresh N.N.N. medium the transformation into crithidia forms which usually occurs does not take place. They have investigated the reason. The same authors (p. 571) have prepared an antigen from *T. cruzi* which is a mass of disintegrated culture forms suspended in a saline solution of methionate—this ensures retention of antigenic properties for a considerable time. With this, complement fixation tests have been performed and correlated with agglutinin and precipitin reactions. The tests revealed fluctuations in the immune state. Immunity shows itself early in infection, when the reticulo-endothelial system is mobilized, and increases as the blood is invaded—the development of leishmania forms is a defence against this vigorous immunity for these forms develop into trypomastotes when grown in medium lacking immune bodies. In the body antibody formation decreases when the leishmania forms predominate.

ROMANA and GIL (p. 405) describe the preparation of an antigen for use in the complement fixation test in Chagas's disease. This test is positive only in that disease with the exception that weak reactions are given in cutaneous leishmaniasis. The authors give details of their results.

HAUSCHKA *et al.* (p. 1054) have shown that infection with *T. cruzi* significantly retards the growth of certain tumours in mice.

EARLE (p. 53) reports a case of Chagas's disease which cleared up, apparently as a result of intravenous administration of penicillin.

Charles Wilcocks

RABIES

REMLINGER, P & BAILLY, J La rage Etudes cliniques, expérimentales et immunologiques [Rabies Clinical, Experimental and Immunological Studies] pp v+192 [Bibliography] 1947 Paris Librairie Maloine, 27 rue de l'École-de-Médecine [18s 6d]

The volume under review summarizes 320 studies on rabies made between 1903 and 1946 by Remlinger and his collaborators. Of these studies, 169 are by Remlinger, 4 by Bailly, 135 conjointly, and 12 by one or other of the authors assisted by LEGER, TEPPAZ, BEL, CURASSON or MICHEL.

Although it is in no sense a textbook on rabies, nevertheless, thanks to the authors' admirable arrangement of the subject matter and to their clear and concise treatment of a majority of the problems likely to face workers in this field, the volume will form a welcome and valuable addition to the reference libraries of anti-rabies institutes.

While it is true that most of the information now presented in so attractive and readable a form will be familiar to the specialist in rabies and its treatment, yet certain of the authors' conclusions and opinions merit special attention and justify recapitulation.

Rabies virus

Street v Fixed Virus—The "singleness" of street virus is contrasted with the "plurality" of fixed virus—a virus "fixed" only in name. Proof of "singleness" is afforded by cross-immunity experiments with variously derived street virus strains, including those endowed with hypernormal virulence ("renforcés"). Proof of "plurality" of fixed virus is based on the wide variation, ranging from the exclusively paralytic to the purely encephalitic, in the symptomatology of rabies among rabbits used in treatment, particularly as regards the day of death, and on the difference in the resistance of such viruses to attenuating agents and in their pathogenic power for the anterior chamber of the rabbit's eye and for the cellular tissues of man and dog.

The nature of rabies virus—The hypothesis first advanced by Remlinger in 1918 that rabies is due to a chemical substance of a protein nature, on the frontier between the organic and the inorganic, receives support, by analogy, from the work carried out in 1935 by STANLEY and his colleagues on the virus of the mosaic disease of plants. STANLEY was able to crystallize the latter virus, discovering it to be a macromolecule of protein, reproducing itself apparently by a process of autocatalysis. Such a conception, if somewhat at variance with the more popular microsporidial theory of rabies virus (*Glugea lyssae*, *Encephalitozoon rabiei*), is not wholly irreconcilable therewith.

Anti-rabies treatment—The "singleness" of street virus obviates the need for polyvalent or autogenous vaccines, failures of treatment, even in the case of reinforced viruses, are attributable almost entirely to insufficient therapy. Standardization of treatment is a desideratum, to be achieved possibly by providing all anti-rabies institutes with the same strain of fixed virus, one combining a high degree of immunizing power with complete innocuity. Were such standardization to prove acceptable, phenolized killed virus vaccine would bid fair to becoming the product of choice, by virtue of its undoubted efficacy, its keeping properties, the decentralization which its use makes possible and its comparative freedom from neuroparalytic accidents.

A strong plea, founded on the experience of French North African territories, is made not only for canine prophylaxis but also for the treatment of dogs and other domestic animals bitten by rabid animals. For canine prophylaxis, use is made of a 5 per cent fixed virus rabbit-or dog-brain, in 1 per cent phenolized water, inactivated at 37°C, of this vaccine 40 cc are administered on the first

day 24 hours afterwards a further dose of 40 cc. is given. Revaccination annually with 40 cc. is advocated. In the treatment of dogs bitten by rabid animals 3 to 10 injections, each of 40 cc. of the same vaccine, have been followed by encouraging results. Similarly in the case of horses and cattle success has attended the exhibition of 40 cc. of the phenolized vaccine on 3 successive days in severe head bites a further dosage of 40 cc. is administered on the 4th day a total of 120-160 cc. is advised according to gravity of wounding.

Finally the need for an international rabies conference, similar to that held in Paris in 1927 is urged. Items on the provisional agenda suggested include the nature of rabies virus the influence of rabbit passage on the susceptibility of fixed virus to the action of attenuating agents the possibility and desirability of standardization of treatment the neuro-paralytic accidents of treatment the vaccination of dogs before and after having been bitten and the vaccination of domestic animals generally

MALARIA

- I. SHORTT H. E. & GARNHAM P. C. C. Pre-erythrocytic Stage in Mammalian Malaria Parasites. [Correspondence.] *Nature*. 1948, Jan. 4 126.
- II. ——— & MALAMOS, B. The Pre-erythrocytic Stage of Mammalian Malaria. *Brit. Med. J.* 1948, Jan. 31 162-4 4 figs. [14 refs.]
- III. HAWKING F. Pre-erythrocytic Stage in Mammalian Malaria Parasites. [Correspondence.] *Nature*. 1948, Jan. 31 175.

I & II. Attempts to discover the developmental forms of sporozoites of *Plasmodium cynomolgi* in the monkey by the Mammalian Malaria Enquiry (this Bulletin 1947 v 44 966) working in India, by HURF and COULSTON in America [ibid. 1945 v 42 536] and by others have yielded only negative results. The authors of the present notes have been more fortunate, as they have discovered the pre-erythrocytic stages in two monkeys receiving large doses of sporozoites. Of a batch of *Anopheles maculipennis atroparvus* fed ten days before on an infected monkey dissection of 20 showed that all were heavily infected. Accordingly 578 mosquitoes were given the opportunity of feeding on a clean rhesus monkey. Over 500 of the mosquitoes fed. The mosquitoes were then ground in a mortar in 10 cc. of heparinized monkey plasma diluted with normal saline solution. Half the suspension was inoculated intraperitoneally and the other half into the thigh muscles of the same monkey. The suspension showed an average of 5 sporozoites per field of the 1/12" objective.

The monkey was sacrificed seven days later and a complete examination was made. Though all the tissues have not been thoroughly examined, inspection of the liver sections and smears has revealed what is undoubtedly the pre-erythrocytic developmental forms in the shape of multinucleated plasmodial masses measuring 29 to 30µ in longest diameter and containing 200-300 nuclei. In a number of the schizonts are one or more vacuoles. The extent of infection of the liver is shown by the occurrence of 38 schizonts in a section measuring 90 sq mm.

Suspensions of liver, spleen, brain, lung, kidney, peritoneal fluid and heart blood were inoculated to clean monkeys which had remained negative for one month at the time of writing. Similar bodies were found in the liver of a second monkey killed on the 6th day after mosquito feeding and injection of sporozoites. In this case the schizonts were smaller and it was possible to determine that the parasites were in the parenchyma cells.

The importance of this discovery lies in the fact that *P. cynomolgi* resembles *P. vivax* of man very closely, this strengthens the belief that such forms are likely to occur in human malaria.

iii. Hawking, who has been studying the early development of *P. cynomolgi* for some time without success, was shown the preparations of SHORTT, GARNHAM and MALAMOS and returned to his own preparations. In livers of three monkeys which had received sporozoites of *P. cynomolgi* he discovered similar pre-erythrocytic schizonts. One rhesus monkey had been inoculated intravenously and parenterally with the sporozoites from 120 infected mosquitoes. It was killed 7 days, 23 hours later. Large schizonts, 28μ in diameter, were found in the liver, similar forms were found in the liver of a monkey killed 7 days 15 hours after intravenous injection of the ground-up thoraces of 1,000 infected mosquitoes. A third monkey inoculated intravenously with the suspension of 40 infected mosquitoes was killed 5 days later. Schizonts 14μ in diameter were found in the parenchymatous cells of the liver. Inoculation of emulsion of organs of these monkeys was not followed by infection. C. M. Wenyon

BULL. WORLD HEALTH ORGANIZATION (United Nations) 1947/48, v. 1, No. 1, 21-8. **Expert Committee on Malaria**. Extract from the Report on the First Session, Geneva, Palais des Nations, 22-25 April 1947.

The urgent importance of the malaria problem caused the Committee on Epidemiology and Quarantine of the Interim Commission of the W.H.O. to set up an Expert Committee to examine it. This Expert Committee met in Geneva in April 1947, and submitted its report, of which this paper is an extract, in August of the same year.

The Expert Committee formed a natural link with the former Malaria Commission of the League of Nations, but a very different field of work confronted it, for the intervening years had brought about new problems and new solutions, and, indeed, the very conception of the mechanism of malarial infection had itself changed, with the newer discoveries regarding the exoerythrocytic cycle.

The original Report comprises ten sections, a number of which are concerned with administrative questions. The extract under review deals more specifically with certain technical aspects of the problem, notably those relating to suppressive treatment, causal prophylaxis, new synthetic drugs and new means of administration of former ones, and the development of new contact insecticides. All of these subjects have been dealt with fully in this *Bulletin* during recent years. The present paper refers briefly to the successes achieved during and since the recent war in the chemotherapeutic control of malaria and its epidemiological control by means of DDT.

Reference is made to the successful field experiments with atabrin [mepacrine], to the work on the 4-amino-quinolines, sontochin (SN 6911) and chloroquine (SN 7618), the 8-amino-quinolines, such as pentaquine, and the biguanides, of which the most important is paludrine.

The use of DDT as a larvicide and more particularly as a mosquitocide is briefly reviewed. The limitations of its use in the former capacity are noted, and it is pointed out that DDT, especially when used from aeroplanes, may upset the economy and normal biological cycles of a region, from the standpoint of animals, crops and trees.

The value of DDT in destroying the adult vector of malaria is supplemented by its effect on other domestic insects, and it may thus influence indirectly the local morbidity from causes other than malaria.

Large-scale house-spraying with DDT will depend on the budgeting facilities of each country concerned, the Report discusses the economic aspects of this matter and the Committee emphasizes that the time has come when more

effort should be devoted to developing methods for more practical and economical control of malaria with this powerful weapon. It is pointed out that, to maintain a reduced incidence of diseases after successful control by DDT the latter will probably have to be used as a recurring measure, and this will require to be taken into account when over-optimistic health authorities are contemplating a budgetary reduction. *H J O'D Burke-Gaffery*

SPADARO O Indice splenico ed indice parasitario in gruppi di popolazione araba in arrivo nel porto di Massawa. [Spleenic and Parasitic Indices in a Group of Arab Immigrants in Massawa.] *Boll. Soc. Ital. di Med. e Ig. Trop.* (Ser. Entrec.) 1947 v 7 No. 3/4 259-61

The English summary appended to the paper is as follows —

The author has searched the spleen index and the parasite index in a group of natives of the Northern Dankalia and of the Yemen who came to Massawa for work. Both groups have given a comparatively low index.

MAUZÉ, J Contribution à l'étude du paludisme dans les Nouvelles-Hébrides (particulièrement pendant la campagne du Sud-Ouest Pacifique Janvier 1942-Décembre 1943). [Contribution to the Study of Malaria in the New Hebrides, chiefly during the War in the South-West Pacific, January 1942 to December 1943.] *Méd Trop. Marseille.* 1946 v 6 No. 2, 109-33 7 graphs & 1 pl.

There are very scant references in the literature to malaria in the New Hebrides. In collecting material for this report the author expresses indebtedness to assistance given by colleagues of the United States Forces during their stay in this island group.

The New Hebrides archipelago lies between New Caledonia, in the south, and the Solomon Islands, and about midway between Fiji and the east coast of Queensland. More than 40 of the islands are inhabited some of these are very small, 120 to 1,200 acres, or even less. The largest island, Espiritu-Santo covers an area of 5 000 square kilometres. The second largest, Mallicolo is about half that size. The islands are of both volcanic and coral formation volcanic activity is manifest in many of the islands. The kanaka population probably does not exceed 50 000 no census has ever been taken. In addition there are 939 French English and half-castes, most of whom live in Vale, the capital in the island of Vati.

The New Hebrides have always had an evil reputation for malaria. Hospital and dispensary attendances during three recent years show it to be the most prevalent disease malaria 4,267 pulmonary diseases 2,531 yaws 942, amoebiasis 885 syphilis 502, gonorrhoea 457 and helminthiasis 298. Seven weeks after the installation of a contingent of United States marines in the island of Vati, 47 per cent. of its strength were incapacitated by malaria.

P. falciparum is the most prevalent parasite, about 75 per cent. of all infections; *P. malariae* about 15 per cent. and *P. vivax* about 10 per cent. Serious clinical forms of malaria are relatively rare.

The only *Anopheles* found in the New Hebrides is *A. punctulatus* or *moluccensis* (now known as *A. punctulatus foveolatus*) of which detailed morphological and biological descriptions are given. It is ubiquitous. It has a great variety of breeding places in the dry season larvae are found in rivers streams, springs, irrigated land, seepages and open wells, and in the rainy season in many collections of casual water as well. The water may be clear turbid stagnant, saline or almost pure rain water and with or without vegetation. The only

waters in which larvae have not been found are open surfaces of running water, and water in broken coconut shells and holes in tree trunks

The New Hebrides mark the southernmost extension of anophelines and malaria in the Pacific in New Caledonia there are neither

PENIDO, H M Alguns aspectos da epidemiologia e controle da malaria na area do Rio Doce [Certain Aspects of the Epidemiology and Control of Malaria in the River Doce Area] *Rev Serviço Especial de Saude Publica* Rio de Janeiro 1947, v 1, No 1, 61-76, 1 map & 1 chart English summary

In this contribution to the first inter-American Congress of Medicine, the author outlines the malaria problems and malaria control measures applied in 33 townships situated along 660 kilometres of the Vitória-Minas Railway. From Vitória, a coastal town in the State of Espírito Santo, the railway runs north 950 kilometres to reach the River Doce near Barbados. There it turns westward and enters the State of Minas Gerais, it runs alongside the River Doce to Ipatinga (458 km). From Ipatinga it runs along the valley of the Piracicaba River, a tributary of the Doce, to Dezembargador Drummond.

The intensity of malaria varies considerably in places along the track from Vitória to Barbados in Espírito Santo. A random sampling of the blood of persons living in 12 places in May of each of four years showed Alfredo Maia to be the most heavily infected, the percentage of positive slides varying from 11 to 30.8. Along the whole railway, *A. darlingi* is the most important vector, the only one except in the first hundred kilometres from Vitória where *A. albicans* is also very prevalent. In the neighbourhood of Vitória, *A. aquasalis* also transmits malaria. The oöcyst rate of 781 *A. darlingi* dissected was 7.5 and of 226 *A. albicans* 1.3 per cent. The examination of patients attending medical posts along the first 150 miles of track showed that *P. vivax* infections were more numerous than *P. falciparum* infections, except in March and April, the end of the rainy season. *P. malariae* infections were rare.

The first two hundred kilometres of the line up the Doce Valley are practically free from malaria, the river bed is narrow and confined, but from Derrubadinha to Dez Drummond, 210 km, settlements on the banks of the Doce and Piracicaba Rivers are intensely malarious. Positive findings in samples of blood films taken in the month of May in four consecutive years in 21 localities show the intensity of infection, in one case the infection rate was 50 per cent. Dispensary records show that in this part of the line also, *P. vivax* exceed *P. falciparum* infections in number except in the rainy months February to May. In April *P. falciparum* infections were more than double those of *P. vivax*.

The rainy season begins at the end of October or early November and 1,500 mm of rain fall in five or six months. The river overflows its banks and actual and potential breeding places for *A. darlingi* are enormously increased. Antilarval control becomes almost impossible, epidemic malaria ensues, its severity being determined by the nature of the rainfall. In the dry season, however, antilarval measures have been carried out with success, chief reliance has been placed on Paris green and small drainage work. The method of work is described.

DDT promises to provide a much more economical method of malaria control in areas that have as low a density of population as has the Doce Valley. A start has been made. An aqueous suspension of DDT has been applied at the rate of 2 gm per square metre. It is proposed to treat the houses three times a year. [For details of control measures used, see BRAGA *et al.* below p 408.]

SCHWETZ, J. Sur le anophèles et le paludisme endémique et épidémique des noirs dans les régions de hautes altitudes de l'Afrique intertropicale. [The *Anopheles* and the Endemic and Epidemic Malaria of Africans in Elevated Regions of Tropical Africa.] *Rev. de Malariologie*. 1947 Oct. v 28 No. 5 227-33.

This paper is a concise summary of the results of numerous investigations carried out by the author in the Belgian Congo. All the facts have been described in previous publications and have been duly noted in this *Bulletin*. Chief consideration is given to the *Anopheles* and malaria at high altitudes along the eastern frontier of the Belgian Congo [this *Bulletin* 1947 v 41 789].

WOLFE, J. Sur la faune culicidienne de l'agglomération de Coquilhatville. (Troisième note.) [The Mosquitoes in the Coquilhatville Region.] *Ann. Soc. Belge de Méd. Trop.* 1947 June 30 v 27 No. 2, 263-71 1 fig. & 1 chart on pl.

In 1946 the author continued investigations which he had made previously into the breeding places of *Anopheles mouchelet* along the banks of the river Congo but had no success because of the backwash caused by the boats which continually pass up and down the river. In backwaters along the Rudi river the water was too foul to admit of breeding by this mosquito and so he comes to the conclusion that most of the *A. mouchelet* that infest Coquilhatville come from the islands in the river (Congo).

Brief notes on the breeding places of species of *Aedes* are given and there is a list of 6 species of anophelines and 44 culicines recorded in 1944 and 1945 which shows that the common species are present all the year round.

WAMBON M., WOLFE, J. & LEBIED B. Comportement de l'*Anopheles* (*Myzomyia*) *mouchelet* EVANS. [The Bionomics of *Anopheles mouchelet*.] *Reu. Travaux Sci. Méd. Congo Belge*. 1947 July No. 6 39-62 2 charts. [25 refs.]

This account of the bionomics of *Anopheles mouchelet* is the result of observations made at Coquilhatville and at Léopoldville in the Belgian Congo. Data are given and compared with those obtained by other workers at Stanleyville and Yangambi and, where relevant with those for *A. gambiae* because though this anopheline is more common in some places at certain times, it is not so common as *A. mouchelet* at Coquilhatville. Matters discussed include numerical abundance and seasonal prevalence, types of breeding places and larval requirements, the influence of distance between breeding and feeding places, outdoor and indoor resting places, longevity and feeding habits of the females and their infectivity with the plasmodium of malaria.

For breeding, this mosquito requires fresh water constantly replenished and shaded—these conditions it finds on the alluvial islands in the river (Congo) and even when the water rises at flood time larvae may be found among dense masses of reeds at the downstream ends of the islands where they are sheltered from the current. Larvae are also to be found among floating vegetation which has broken away from the islands and the river banks. At Léopoldville (Stanley Pool) the islands are not so numerous and the height of the water reduces the number of breeding places, thus limiting the output of adults. In mid-November about three weeks after the floods have reached their maximum breeding places are again available and in January the mosquito catches in the prison which is the nearest catching station to the Pool, yield three times as many *A. mouchelet* as *A. gambiae*.

Outside haunts of this anopheline at Coquilhatville are found among trees, in the shade and not far from the breeding places, but they have not yet been discovered at Léopoldville. A study of the feeding habits and the ovarian development of females has shown that the majority found in houses possess ovaries in stages I and II. Typical figures for outdoor catches give 20 per cent females with ovaries in stage V and 60 per cent for females which have not fed. In fishermen's huts on the islands, examination of 500 females of *A. mouchei* showed 31 per cent with stage V ovaries and only 3 per cent in stage I. Sporozoite rate at Coquilhatville is 0.072 per cent, whereas at the fishermen's huts at Stanley Pool the rate is 6.3 per cent.

From these observations and a great many more, the authors conclude that, *A. mouchei* is short-lived; that the female needs only one blood meal to mature the eggs, that it enters houses, rests for some time before feeding and then leaves immediately to digest the meal and to mature the eggs outside; there is evidence also that the sporozoite index is fairly constant in any one locality, and varies only according to the distance from the breeding places.

In the laboratory, *A. mouchei* has been observed to deposit an average of 200 eggs per female; eggs hatch in 12 to 24 hours and the larval stage lasts 10 to 11 days. The whole life cycle can be completed in 13 to 14 days and males and females emerge in approximately equal numbers. The authors have not yet succeeded in establishing a laboratory colony. The discovery of a blue coloration infiltrating the thoracic muscles is a matter for future investigation.

LAUTERBURG-BONJOUR, M. Die Abwehrfunktionen des menschlichen Körpers gegen die Malaria. [Defensive Functions of the Human Body against Malaria.] *Schweiz med Woch* 1947, Dec 27, v 77 No 52, 1359-62

In his discussion of immunity in malaria, the author concludes that it is not a simple process but is very complex. Apart from normal phagocytosis there is a phagocytosis which is stimulated by parasitic and antitoxic substances which have been demonstrated in the blood. The immunity is strongly specific, not only for the kind of malaria but for the particular race of parasite. In endemic areas a latent malarial infection is of value in that it prevents reinfection with the same race of parasite. Such a latent infection in persons going to new malarial localities is not able to prevent infection with any new race to which there is exposure.

BOYD, M F & KITCHEN, S F. On the Homogeneity or Heterogeneity of *Plasmodium vivax* Infections acquired in highly Endemic Regions. *Amer J Trop Med* 1948, Jan, v 28, No 1, 29-34

It was noticed that some soldiers returning to the USA from highly endemic areas in the Pacific, developed repeated attacks of *P. vivax* malaria. The intervals between these attacks were usually short, and the febrile episodes were thought to be recrudescences rather than relapses (as defined by Boyd & Kitchen, this *Bulletin*, 1945, v 42, 174). The men had been on daily suppressive quinine and the malaria did not appear until this therapy was discontinued. The authors considered that several strains of *P. vivax* were acquired and either that all these strains were reactivated simultaneously during the recrudescences or that some strains would recover from the "quinine induced lethargy" earlier than the remainder. If the first explanation were correct, the parasites of the various recrudescences should show complete cross immunity. On the other hand, if each recrudescence represented an infection by heterologous strains, then cross immunity should be lacking.

Mental patients were therefore hyper immunized against one of three strains recovered from a young soldier who had suffered from many attacks of *P. vivax* malaria contracted in the Pacific. The results indicated that two of the strains appeared to be closely allied if not identical while the third showed a substantial difference.

MAKARI J G. Intradermal Test in Malaria. Parts I, II & III. *J Trop Med. & Hyg.* 1948, Apr-May & June-July v 49 Nos. 2 & 3 23-9 47-54 7 figs. [19 refs.]

The antigen for this test was obtained from the blood of a chicken heavily infected with *P. gallinaceum*. Heart blood was put in small oxalated tubes, 2 cc. in each. Plasma was separated by centrifuge and discarded. The corpuscles were washed four times with saline and then dried *in vacuo*. After 2 months they were transferred to clean test tubes and sealed, and kept at room temperature, about 30°C. for two months. To prepare the stock solution the powder was triturated in a mortar. A suspension of 1 per cent. of this powder in 0.5 per cent. carbolized salt solution was then prepared, and incubated for 24 hours at 37°C. It was then passed through a Seitz filter and tested for sterility. This sterile fluid was used in the intradermal tests.

In making the test 0.1 ml. was injected intradermally on the forearm. Readings were taken after 24 hours. The diameter of redness was measured in millimetres and the results were recorded as follows

| | |
|-----------------|------|
| 0-4 mm. | 0 |
| 5-9 mm. | + |
| 10-14 mm. | ++ |
| 15-19 mm. | +++ |
| 20 mm. and over | ++++ |

Of 70 persons with no history of malaria, 63 gave a negative reaction, 5 had a + and 1 had a ++ reaction.

Of 71 patients who had had malaria 18 months previously 65 gave a positive intradermal test.

Of 31 others having a history of malaria within 3 years or more, 29 gave a positive test.

The sensitivity of the tissues to the malarial antigen appears to reach its peak from 2 to 3 months after an attack. In the majority of cases it is never lost completely.

II. Another antigen N was prepared from normal chicken erythrocytes in the same manner as was the malarial antigen M from malaria-infected erythrocytes described above. Antigen N gave positive reactions in 14 per cent. antigen M in 20 per cent. of 70 boys with no history of malaria. These pseudo-positive reactions were all weak (+). Of the false reactions to antigen N 90 per cent. were in individuals of blood groups O or B in both cases having anti-A antibodies which would react with the A like Forssman antigen found in normal chicken red cells. Antigen N gave weak positive reactions in 40 per cent. of the malarial series. Malarial infection stimulates the production of heterophile antibodies. The control testing with normal antigen N should always accompany the testing with malarial antigen M to eliminate a number of false positive reactions.

III. The author believes that a combined use of the intradermal test and the cephalin cholesterol flocculation test (this *Bullet.* 1948, 43, 623 1947 v 44 279) would assist in the detection of chronic masked and latent forms of malaria and the determination of the activity of the infection in assessing the rôle of malaria in determining false positive serological reactions.

in ruling out malaria in the blood plasma programmes , and in solving problems created by returning malaria carriers from overseas Norman White

MAKARI, J G Altered Tuberculin Sensitivity in Chronic Malaria *J Trop Med & Hyg* 1947, Sept, v 50, No 9, 183-5 [11 refs]

The author has submitted a number of Armenian refugees, in Syria, to the tuberculin test, the intradermal malaria test [see above], and the cephalin-cholesterol flocculation test. There were 58 persons with chronic malaria, and 60 in whom malaria was excluded by negative history and negative intradermal test.

In general, the results indicated that the incidence of positive tuberculin tests (OT, 1 in 1,000) was higher (41.4 per cent) in those with chronic malaria than in the controls (23.3 per cent) and that the difference is statistically significant. Moreover, the incidence of positive tuberculin tests appeared to be related to the activity of the malaria, as estimated by the cephalin-cholesterol test, and to the sensitivity of the tissues in response to the malarial antigen.

The author discusses the possibility that there may be a relationship between the proteins of the tubercle bacillus and the malaria parasite, that the tubercle bacillus may have a predilection for tissues damaged by malaria, and that persons with chronic infections may react more readily than normal persons to antigens other than those from the organism infecting them.

[The author places a high degree of reliance on the cephalin test, but in a previous paper (this *Bulletin*, 1946, v 43, 623, 1947, v 44, 279) he claimed accuracy of only 91.4 per cent for it. It seems likely that the cumulative errors of all these tests might be considerable.] Charles Wilcocks

SCHEIFLEY, C H Malaria a Note on its Latency and Report of a Case *Proc Staff Meetings Mayo Clinic* 1947, Feb 5, v 22, No 3, 49-52

"It is commonly thought that a primary attack of malaria may occur a year or more after cessation of suppressive medication. A review of the literature failed to reveal any well-documented reports to bear out this assumption. In the case reported in this paper, benign tertian malaria developed twelve months or more after suppressive therapy had been discontinued."

BOYD, M F A Note on the Chronicity of a Quartan Malaria Infection *Liber Jubilaris J Rodham (Soc Belge Méd Trop, Brussels)* 1947, Dec, 99-101

"A naturally induced *P. malariae* infection has persisted in a latent chronic condition in a colored patient for a period of 4,305 days, or 11 years, 9 months, 14 days since the original inoculation."

SOYSA, E Malarial Episodes A Clinical Study of Atypical, Pernicious and Lethal Cases selected from among 10,000 Malarial Patients admitted to Military Hospitals in Ceylon *J Roy Army Med Corps* 1947, Nov, v 89, No 5, 205-22, 3 figs

To illustrate the diversity of clinical features that may result from malarial infections the author has selected twelve cases from the 10,000 that were treated in two military hospitals in Ceylon during a period of four years. All the cases present unusual features and are fully and well described. They illustrate apyrexial malaria, hyperpyrexia, algid malaria, cerebral malaria, malaria encephalopathy, malarial neuritis, malarial jaundice, malarial dysentery,

severe malarial anaemia, malarial leucopenia, malarial haemoglobinuria and malarial pneumonia. The nature and length of this interesting paper preclude a summary
Norman White

MELLINKOFF S. M. & HIGGINS J. R. The Heart Rate in Malaria; a Review of Ninety Cases. *Ann. Intern. Med.* 1947 Sept. v 27 No. 3 433-40 4 figs. [10 refs.]

This paper concerns the heart rate in 90 patients suffering from malaria contracted for the most part in the Philippine Islands. In most cases, the appearance of clinical symptoms had been delayed by the administration of prophylactic doses of atabrin. There were 85 patients with *P. vivax* infections, 2 with *P. falciparum* and 3 with *P. malariae*. The pulse readings record the greatest relative tachycardia observed at the height of each initial fever. After the subsidence of fever and malaise the resting pulse rate was recorded in each case, an hour after the patient had awakened from a good night's sleep, the interval hour having been spent in bed. The results of the study show that malarial fevers may be accompanied by rates of heart beat ranging from tachycardia like that which characterizes many bacterial infections to bradycardia like that of typhoid fever. About one-fourth of these patients had relative bradycardia.

BOSHER, B. Neuropsychiatric Manifestations during the Course of Malaria. Experiences in the Mediterranean Theater in World War II. *Arch. Neurol. & Psychiatry* 1947 July v 58 No. 1 14-23 2 figs. [Refs. in footnotes.]

The author deals with his experiences in the Mediterranean war area, where malaria was a common disease among American armed forces with special reference to the neuropsychiatric complications of malaria that were encountered. These complications simulated meningitis, encephalitis, cerebral tumour, vascular lesions and psychiatric disorders. Such cerebral forms of malaria were not exclusively caused by *P. falciparum* infections. *P. vivax* was sometimes incriminated. The clinical history of an illustrative case is described.

A man aged 26 fell ill with a chill and slight fever. Two examinations of the blood were made but no parasites were found. Symptoms of meningo-encephalitis developed rapidly with characteristic changes in the spinal fluid, the suspicion of a virus infection was not confirmed. Convulsions developed and the diagnosis of epilepsy was considered but the presence of coma, a temperature of 102.20 F. and meningeal symptoms negatived this. Then followed an afebrile period of several days during which the cerebrospinal fluid became normal, but evidence of transient focal disturbances in the brain remained. Still no malaria parasites were to be found. On the 8th day a generalized convulsion occurred, followed by a Jacksonian fit on the right side, sodium amytal aborted a threatened status epilepticus. Four days later a right homonymous hemianopia was detected, and persisted. On the 19th day of illness the temperature rose to 101.8° and *P. vivax* was found in the blood. Quinine was administered. All the symptoms cleared up quickly except the hemianopia. The case was undoubtedly one of malarial meningo-encephalitis with multiple neuropsychiatric manifestations. Norman White

ANDREWS J. C. & CONRATZER, W. E. The Metabolism of Cinchonine in Dogs and in Man. *J. National Malaria Soc.* 1947 Dec. v 8, No. 4 248-50. [10 refs.]

The authors showed previously that cinchonine was absorbed more rapidly than quinine from the isolated intestinal loops of dogs. HATT [this Bulletin

1945, v 42, 178] on the other hand, found that only low concentrations of the former were present in human plasma after oral administration compared with those of the other common cinchona alkaloids, indicating a possible difference in the rate of absorption of the two optical isomers cinchonine and cinchonidine. When the four alkaloids were given intravenously to man, HIATT & QUINN [this *Bulletin*, 1945, v 42, 778] found that their distribution in the body was similar. It is possible therefore that the rate of metabolic breakdown varies in the case of these different alkaloids. Data were therefore obtained on the blood levels and urinary excretion of cinchonine in man and dog by means of the intestinal loop method of the authors [this *Bulletin*, 1945, v 42, 534] in the animal experiments. The results indicated that cinchonine is metabolized more rapidly than cinchonidine or quinine in man. In the dog the rate of metabolic breakdown appeared to be much slower. The results are of interest, since some authors believe that the antimalarial effect of cinchona alkaloids is due to a metabolic product of those substances.

J D Fulton

CHEN, G. Influence of Pamaquine and Atabrine on the Enzymatic Degradation of Quinine. *Proc Soc Exper Biol & Med* 1947, Nov, v 66, No 2, 313-14, 3 figs

KELSEY & OLDHAM [this *Bulletin* 1944, v 41, 260] found that, of various animal tissues, rabbit liver was richest in the enzyme, termed by them quinine oxidase, which converted the alkaloid to the substance which MEAD & KOEFLY [ibid, 1945, v 42, 9] characterized as a 2-hydroxy derivative. A method has now been developed for the quantitative assay of this enzyme, and its inhibition by plasmoquine (pamaquin) and atabrin (mepacrine) have been investigated. For this purpose, fresh rabbit liver was homogenized in Ringer-Locke solution. On centrifuging, all the enzymic activity was found to be present in the supernatant fluid. The latter was therefore used in all the experiments, in which quinine in Ringer-Locke solution and the enzyme were incubated at 39°C for appropriate times. Enzyme action was then inhibited by the addition of an equal volume of 4 per cent caustic soda. The unchanged quinine was estimated by the fluorometric method of CHEN & GEILING [ibid, 1945, v 42, 348] in a Coleman photofluorometer, with the use of suitable filters when plasmoquine and atabrin were present. The relationship between the percentage degradation of quinine and the logarithm of liver concentration used was linear except in the early stages of the reaction and a roughly similar relationship held when the former values were plotted against the logarithm of reaction time. By choosing a reaction time of one hour, the graphs allowed the activity of an enzyme preparation to be determined. Both plasmoquine and atabrin inhibited the conversion of quinine. While the mode of action of these substances is not quite clear, it is believed that they act on the enzyme rather than on the substrate.

J D Fulton

DEARBORN, E H. The Distribution of Quinacrine in Dogs and in Rabbits. *J Pharm & Exper Therap* 1947, Oct, v 91, No 2, 174-7

"The concentration of quinacrine in the plasma of rabbits and dogs shows marked variation. There is no significant correlation between the concentration of quinacrine in the plasma and that in the tissues of rabbits and dogs. The concentration of quinacrine in muscle and its ratio to the concentration in the plasma tend to increase in dogs on a constant daily dosage."

TRACER, W. The Rate of Asymptomatic Malarial Infection in White and Negro Service Troops taking Suppressive Atabrine. *Amer J Hyg* 1947 Nov v 46 No 3 338-40

The author in collaboration with RAWC and others, has previously shown that malarial parasites may sometimes be found in thick blood films from men taking adequate suppressive doses of mepacrine and having no clinical symptoms of malaria [this *Bulletin* 1947 v 44 503]. In Finchhafen New Guinea, he made a study of three pairs of Army units, one unit of each pair consisting of whites, the other of negroes. The units of each pair were living under strictly comparable conditions as regards the risk of malaria infection. The men were all taking, or supposed to be taking, 0.1 gm. of mepacrine a day. The results of the study during the 4 to 8 weeks period of observation were as follows—

| | Unit | | | | | |
|--|-------|-------|-------|-------|-------|-------|
| | A | B | C | D | E | F |
| Race | White | Negro | White | Negro | White | Negro |
| Men studied | 87 | 82 | 93 | 85 | 108 | 102 |
| Average smears per man | 5.2 | 5.5 | 3.8 | 3.8 | 3.7 | 2.8 |
| No. with one positive smear | 18 | 11 | 20 | 9 | 20 | 17 |

Most of the parasites found were ring forms. A few old trophozoites were seen, but only one gametocyte (*P. vivax*). It is probable that all the parasites were *P. vivax*. Only one man had three positive smears (Unit E) he had parasite counts of 132 and 55 parasites per 500 white cells in three successive weeks, but had no symptoms of malaria. Very few of the other positive smears contained more than 4 parasites per 500 white cells. The author has previously shown that the finding of these occasional parasites bears no relation to the mepacrine blood level.

PARK, D. Mepacrine Psychosis. *J Mental Sci* 1947 Oct. v 83, no. 293 758-71 [12 refs.]

Not all cases of psychosis in patients with malaria treated with mepacrine are necessarily true cases of mepacrine psychosis. It is possible that the symptoms began before the exhibition of mepacrine and were precipitated either by malaria or by circumstances antecedent to it or the condition was present before mepacrine therapy and was aggravated by the drug. In true mepacrine psychoses, the symptoms are precipitated by the administration of mepacrine. Twenty three cases of true mepacrine psychosis seen in the Middle East are described: all were males and British except for two Palestinian Jews. The proportion of officers and N.C.O. to privates was as 11 to 1 and is said to be high compared with the ratio in the command (the ratio is not given). The most common mental make-up of the patients was schizoid, 6 cases. The aetiology of mepacrine-precipitated cases is thought to be multifactorial and in addition to malaria, emotional stress may have contributed in 7 cases, recent battle stress in 3 and alcoholism in 2 cases. Eleven patients had had one or more attacks of malaria in the 18 months before the psychiatric episode. Three

patients gave histories of previous psychotic breakdowns and in one other psychotic symptoms appeared during a subsequent attack of malaria when quinine and pamaquin were given. Of the 23 patients, only one had been on suppressive mepacrine—he had taken 0.2 gm for 9 months, and the breaking-off of his engagement is said to have precipitated the attack.

The psychotic symptoms appeared when the standard treatment for malaria was 3.4 gm of mepacrine in 6 days. One-third of those affected developed mepacrine psychosis on the third or fourth day of treatment, the remainder usually within 7 days of the end of treatment. In one case, symptoms began in less than three days and in another (included as having been precipitated by mepacrine) not till 3 months after the cessation of mepacrine therapy [on the dose schedule given, it is very doubtful whether more than minimal traces of mepacrine would have been found in the body after this interval].

There was no significant difference in the time of recovery between those developing the psychosis early and those who developed it late.

The most frequent symptoms were schizophrenic and manic in type. Malaria, on the other hand, more commonly produces a depressive reaction. The onset is almost invariably signalized by insomnia and in the non-depressive cases by a sudden change of behaviour, with noisy talkative excitement. The psychotic picture then develops rapidly—there is a brief phase for a day or two of features such as fleeting ideas of influence, loss of personality and reality sense and sometimes transient confusion and disorientation. This is followed by elation, euphoria and delusions of an exalted character. Eight typical case histories are recorded.

Fourteen of the 23 patients recovered within 6 months of the onset of symptoms, the quickest being in 14 days, the average 62 days. Those with manic and schizophrenic symptoms recovered most quickly. Mepacrine psychoses occur more frequently in a slightly older age-group than do those due to malaria. Electrical convulsive treatment was used in six cases. 4 of these (two with schizophrenia and two with depression) improved but 2 remained unchanged. The number of convulsions ranged from 2 to 6, averaging 4.6.

Diagnosis requires differentiation from cerebral malaria and from an endogenous or biogenic psychosis.

It is stated that the medical attendant should be on his guard in exhibiting mepacrine to those who have had recent attacks of malaria, show evidence of hepatic derangements, have taken suppressive mepacrine in large doses or suffer from any factors which delay the excretion of mepacrine.

The danger signals which are said to call for the stoppage of mepacrine in the treatment of a malarial attack are staining of the skin and the occurrence of insomnia, alteration of conduct, restlessness, talkativeness and confusion.

[Few will agree with the contention that staining of the skin necessitates cessation of mepacrine therapy. Those in army commands serving in hyper-endemic malarial areas were almost all tinted yellow by mepacrine—eccentric some of them may have been—but they were not on the verge of a mepacrine psychosis.]

BUONOMINI, G & MOTTA-DIANA, A. Trattamento abbreviato con acridinici dell'attacco malarico sua utilità nella pratica dispensariale [Short Treatment with Acridine of the Malaria Attack and its Suitability for Dispensary Practice]. *Settimana Med* 1946, Aug 3-31, Year 34, n.s., v 2, Nos 31/35, 64-8, 2 figs.

The 'standard' treatment of malaria attacks in Italy with Italchina [an acridine derivative, see this *Bulletin*, 1941, v 38, 34], has consisted hitherto

in the administration to patients 14 years of age and upwards, of 0.3 gm. a day for five days in *P. vivax* infections, and for seven days in *P. falciparum* infections. The authors report the treatment of 211 cases of *P. vivax* malaria and 54 cases of *P. falciparum* malaria with larger doses for a period of 4 days only in both types of infection the doses being 0.5-0.6 gm. a day for adults. The results are compared with those obtained by the treatment of 1813 cases by the "standard" method. The observations were made in an endemic area of Szech. The blood of all patients was free from parasites on the 4th day. In 98 per cent. of the *P. vivax* infections on the 3rd day. There was no significant difference in the incidence of relapses after the two methods of treatment. Symptoms of intolerance to the drug were absent or insignificant in the vast majority of cases. One patient developed transient psychotic symptoms.

The short system of treatment possesses obvious advantages for dispensary practice in rural areas especially and is recommended. Norman White

Pinto, G. de S. Sobre a ação da paludrina nos acessos de malária. [The Action of Paludrine in the Treatment of Malarial Attacks.] Reprinted from *Folha Ued.* 1947 Aug 25 12 pp

A severe outbreak of malaria in the early months of the year occurred in Itapema a district in the Guarujá município in the Isle of Santo Amaro near Santos Brazil. The outbreak was attributed to the influx of very large numbers of chronic malaria sufferers. [The vector *A. tritaeniorhynchus* was surprisingly difficult to find, only exceptionally being captured in houses.] About 80 per cent. of the infections were caused by *P. vivax*.

Paludrine was used in the treatment. 11068 patients with acute malaria. Of 557 patients treated with a single dose of 2 tablets, 0.20 gm. febrile symptoms were promptly suppressed in 88.4 per cent. When 4 tablets were given in two doses, the success rate was 97.7 per cent. (93 cases).

Kierland R. R. & McCright W. G. The Termination of Therapeutic Malaria with Chloroquine. *Amer J Syph* 1948 Jan v 32 No 1 57-8.

The authors refer to previous work on the use of chloroquine in the treatment of malaria and especially in acute relapsing *P. vivax* infections this *Bulletin* 1948, 45-57.

They have used chloroquine to terminate therapeutic malaria in 43 patients suffering from central nervous syphilis who had been inoculated therapeutically with a strain of *P. vivax* which had been in use for more than 20 years. The inoculation took the form of an intravenous injection of 5 cc. of an infected whole blood direct from patient to patient. The incubation period varied from 1 to 14 days and each patient had between 2 and 10 paroxysms before termination was attempted. The result obtained with chloroquine could not be shown to be affected by the incubation period or by the number of paroxysms.

Each patient was given 1 gm. of chloroquine followed in six hours by 0.5 gm. and then 0.3 gm. again in twenty-four and forty-eight hours (total 1.8 gm.). In two cases a total 1.3 gm. was given. The chance of relapse was reduced when the drug was given after the paroxysm temperature had fallen below 103°F and thus also reduced the likelihood of an additional paroxysm. In 1 case, no febrile episodes occurred after the treatment had started but in 4 an additional paroxysm occurred within the next four hours. In all these 4 cases the drug had been given when the temperature was rising.

Only one patient reported a side-reaction, namely a mild and transient gastro-intestinal upset no skin reactions were reported

In 14 cases in which the blood was examined for parasites after chloroquine had been given, parasites were found to have disappeared within 24 hours of the initial dose in 2, within 48 hours in 4 and within 72 hours in 7. In one case, the parasites persisted until the 5th day. One case was negative microscopically throughout. No relapses have been noted during follow-up periods of 2 to 8 months after treatment.

WALTON, G A On the Control of Malaria in Freetown, Sierra Leone I *Plasmodium falciparum* and *Anopheles gambiae* in relation to Malaria occurring in Infants *Ann Trop Med & Parasit* 1947, Dec, v 41, Nos 3/4, 380-407, 7 figs [56 refs]

The author was the first medical entomologist appointed to the Government of Sierra Leone. At that time, 1943, malaria control, on a large and comprehensive scale was begun as an urgent wartime necessity. By co-operation with the three Services, mosquito breeding in the western and eastern rural areas and Central Freetown was controlled by larvicides. An extensive network of mosquito catching stations indicated the anopheline house population from week to week. This paper is an assessment of the effect of these measures during the period June 1944-June 1946, on malaria incidence in Freetown.

Freetown has some 8,000 houses and population of 80,000, and is situated along a coastal plain less than a mile wide and backed by heavily wooded mountains. Humidity is high all the year and there is a heavy rainfall of about 130 inches per annum, five months are almost dry, but July and August have 35 inches each. That the house population of *Anopheles gambiae* was very markedly reduced is shown by the following table —

Number of female *A. gambiae* per 1,000 rooms per month in Freetown June 1944 to May 1946

| June | July | Aug | Sept | Oct | Nov | Dec | Jan | Feb | Mar | Apr | May |
|------|------|-----|------|-----|-----|-----|-----|-----|-----|-----|-----|
| 261 | 447 | 189 | 55 | 8 | 4 | 7 | 11 | 10 | 4 | 7 | 64 |
| 330 | 116 | 37 | 18 | 4 | 1 | 15 | 23 | 20 | 27 | 20 | 147 |

The anopheline infective density is a means of expressing the malaria-transmitting ability of an anopheline population. The number of infected *A. gambiae* for each average Freetown room from October 1944 to March 1945 is calculated at 0.07. In other words, there was on the average only one infected *A. gambiae* in every 14th room per 18 months. Applying this conclusion to the human population of Freetown for that period, one in 56 persons would receive an infected mosquito bite—this figure is a maximal estimation.

Malaria in African Infants

Parasite Infestation of Infants.—Data of infestation placed in age-groups of 3 months and plotted semi-logarithmically is as follows—

Fig. 1.—Graph showing the rate of increase with age in percentage malaria infestation of infants. The black curve is based on the recognition of not less than four trophozoites; the dotted curve includes all positive findings, but the true curve of infestation is probably even higher since some infections must have been missed. Fig. 7 is original.

Effect of Mosquito Control.—The comparable numbers of infected lates per room per year in an eastern rural suburb (Kissy) in 1931 and in Freetown in 1931 and 1945 were roughly .50, .30 and 0.07.

Parasite infestation in age groups in the same areas for the years 1931 and 1945 is illustrated as follows—

Fig 2—The effect of mosquito control on the parasite index of infants at different ages. The tall black columns show the parasite-indices of infants living in the rural village of Kissy close to Freetown in 1931. The white columns show the parasite index of Freetown infants in 1931 and the short black columns show the same for the period 1944-46. [Fig 5 in original]

[That this marked reduction occurred only in Freetown, and not also in the surrounding country, is shown by the work of Davidson in 1946, his summarized results for parasite indices in children were 80 per cent for coastal and 73 per cent for interior villages]

Relation between the Anopheline Infection-Rate and the Malaria Parasite-Rate in Infants

A statistical method is described for estimating the number of infective mosquito bites and the associated parasite-indices, the calculated result is summarized in Table VI below

Rate of Infection of Infants—It was possible to keep track of 50 infants for eighteen months or more, 12 to 15 infections were received, that is 1 in 4. The considerable discrepancy between this figure and the above-mentioned 1 in 56 persons is believed to be due to infections acquired outside the controlled area.

Duration of Infection in Infants—A table summarizes monthly blood examinations of 31 infants up to the 24th month. The difficulty of following-up cases has caused many omissions, but the data do throw some light on the duration of single infections, the average appears to be about 9 months.

Gametocyte Production—It was observed that gametocytes appeared for one month only, during which trophozoites were suppressed. The mean number of trophozoites unaccompanied by gametocytes was 1,000 per 150 fields while the mean number with gametocytes was 14.

TABLE VI

Parasite indices produced group young children by various numbers of anopheline mosquito-bites received per year

| No. of infective bites per child per year | Calculated parasite-rate per cent in young children |
|---|---|
| 0-01 | 0.26 |
| 0-10 | 57 |
| 0-20 | 5.07 |
| 0-30 | 7.50 |
| 0-40 | 8.90 |
| 0-50 | 12.20 |
| 0-70 | 16.60 |
| 1-00 | 22.90 |
| 1-50 | 33.30 |
| 2-00 | 40.50 |
| 3-00 | 54.20 |
| 4-00 | 64.0 |
| 5-00 | 73.70 |
| 7-00 | 83.60 |
| 10-00 | 92.60 |
| 20-00 | 99.45 |
| 30-00 | 99.96 |
| 50-00 | 99.99 |

Sensitivity of Infants—From the data available it would appear that contrary to what would be expected the intensity of infection, as measured by the number of trophozoites in the blood increases with age at least up to the age of 15 months. Apparently the infants become increasingly susceptible as they grow older. The figure below attempts to portray the change in parasite quantity with age.

Previous Work on African Infants—A summary is given of previous work in the light of this and his own experience the author concludes that, for some reason, very young infants are not bitten by anophelines to the same extent as older children or that when bitten by infective mosquitoes they possess some mechanism which prevents the appearance of plasmodia in the peripheral blood.

Whatever brings about active proliferation of the reticulo-endothelial system of the mother might well do the same to the unborn child and hence the newly born infant would be ready to deal with its first infection.

[The author has made most valuable contribution to knowledge of malaria transmission in addition to proving the efficiency of larvicidal methods of control when backed by sound organization he claims a virtually 100 per cent. effective result. This mass of information with a full list of references, requires to be digested in the original by readers interested in the subject.]

Fig 3—Three-dimensional hypothetical representation of the variation of intensity of parasite infestation at different ages

The horizontal axis shows age increasing from left to right the older age groups are foreshortened. Based on the age group scale the histogrammatic representation in the vertical axis depicts the change in percentage parasite infestation with age. Superimposed on this is the graphic representation of the same data. The depth of the receding columns represents the mean number of parasites per unit volume of blood (intensity) in each age-group the scale being on a horizontal axis at right angles to the axis depicting increasing age. The differences in the intensities of parasite infestation at different ages are greatly reduced nevertheless the great variation in the degree of parasitization at different ages is quite clearly shown. The receding curve passing through the distal margins of the columns represents the change in parasite quantity with age [Fig 6 in original]

R Ford Tredre

THOMSON, R C Murhead. The Effects of House Spraying with Pyrethrum and with DDT on *Anopheles gambiae* and *A. melas* in West Africa. *Bull Entom Res* 1947, Dec, v 38, Pt 3, 449-64 [23 refs]

A. gambiae and *A. melas* are well known house-frequenters by day, but the author submits evidence of out-door resting places and is of opinion that the number of mosquitoes caught by routine methods in houses by day may be only a small proportion of the mosquitoes actually feeding there at night. Ninety per cent of feeding by *A. melas* and *A. gambiae* takes place between midnight and dawn, and it is possible for the mosquito to spend only an hour or two of the 48-hour gonotrophic cycle in the house.

Three villages near Lagos were mass-sprayed with "Pyefly" diluted 1 in 59 with kerosene, at the rate of $\frac{1}{2}$ to $\frac{3}{4}$ ounce per 1,000 cu ft, with the results shown above. In the selection of these villages, care was taken to ensure that there was no infiltration of infected mosquitoes from other areas. Even the intensive spraying of the last period failed to bring about a substantial reduction

Spray-killing in Houses with Pyrethrum in Kerosene

TABLE 1

Mass spraying of village houses with pyrethrum in kerosene. Incidence and fecundity of molas and gambusia. December 1942-April 1943

| Treatment | Number and period of collections | Gambusia and molas per 10 bed-rooms | Mosquitoes dissected | Glands positive | Sporozoite rate |
|--|----------------------------------|-------------------------------------|----------------------|-----------------|-----------------|
| Preliminary survey Houses untreated | 8 18/iii to 19/i | | | | Percent. |
| All houses sprayed four times weekly from 19/i | 15 1/ii to 7/iii | 33 | 485 | 17 | 3.5 |
| All houses sprayed six times weekly from 7/iii | 7 14/iii to 2/iv | 11 | 403 | 12 | 3.0 |
| | | 12 | 47 | 18 | 7.3 |

in the numbers of mosquitoes in houses, though the increase in the sporozoite rate may be due partly to the increase in breeding of *A. gambusia* expected at this time of the year.

As a result of the use of experimental huts provided with suitably designed window traps in an area infested with *A. molas* evidence is offered to explain the results of village spraying. In short, in an untreated hut of the local type the number of blood-fed female mosquitoes found resting by day represent $\frac{1}{3}$ to $\frac{1}{2}$ of the total numbers feeding there the previous night but in the hut sprayed daily with pyrethrum in kerosene the numbers found in the hut by day represent only $\frac{1}{3}$ of the total feeding there at night. Pyrethrum in kerosene has an irritant effect on many blood-fed *A. molas* driving them out of the house after feeding. It also has a repellent effect, but it discourages entrance to the house only if an alternative untreated house is a viable female *A. molas* are not attracted to animals nor are they driven to animal feeding by mass spraying of human habitations. They prefer to enter the latter at night to feed and leave almost at once. As a corollary to these conclusions the author observes that however efficient spray killing may be in estimating the total house or room-catch it should not be used in the same house more than once a week, otherwise the results may be affected by a shift of mosquitoes from inside the house to outside resting places.

The author concludes —

The fall in the number of mosquitoes resting by day in houses after spraying is now seen to be caused, not by any great reduction in the population as a whole but rather to a shift from indoor to outside resting places. The number of mosquitoes killed by even the most intensive spraying represents such a small proportion of the whole that the average length of life may be little affected, the parasite rate remaining at much the same level as before.

DDT in Kerosene as a Residual Insecticide

In the light of the observations on pyrethrum the author proceeded to the investigation (by similar methods) of the effects of DDT in kerosene as a residual insecticide. The mass treatment of village houses by the usual methods produced the expected result, namely that house catches fell practically to zero and remained low for the nine weeks of observation.

Behaviour of A. melas in Experimental Huts

TABLE V

Treatment of experimental huts with DDT One hut treated at rate of 100 mgm DDT per sq ft Other hut untreated Catches refer to freshly blood-fed Anopheles (95 per cent melas, 5 per cent gambrie) Window traps record mosquitoes leaving hut after feeding

| | Before treatment | After spraying | | | | | |
|--|------------------|----------------|-----------|------------|------------|------------|-----------|
| | | 1 Week | 2 Week | 3 Week | 4 Week | 5 Week | 6 Week |
| Number of visits | 8 | 5 | 5 | 6 | 6 | 3 | 4 |
| Treated hut { Hut catch Window trap | 77 27 | 0 44 | 0 89 | 1 176 | 0 255 | 1 133 | 0 178 |
| Untreated hut { Hut catch Window trap | 91 25 | 189 56 | 244 12 | 390 223 | 140 294 | 138 123 | 194 35 |

TABLE VI

As in Table V but experimental hut treated at rate of 250 mg DDT per sq ft

| | Before treatment | After spraying | | | |
|--|------------------|----------------|------------|------------|------------|
| | | 1 Week | 2 Week | 3 Week | 4 Week |
| Number of visits | 5 | 4 | 6 | 5 | 3 |
| Treated hut { Hut catch Window trap | 189 56 | 0 2 | 0 28 | 0 157 | 0 82 |
| Untreated hut { Hut catch Window trap | 273 40 | 196 10 | 390 223 | 115 245 | 138 123 |

No dead *Anopheles* were found on the floor-matting of the treated hut, the mortality, during 48 hours after feeding, among mosquitoes leaving the hut was practically nil. By a separate experiment, it was shown that the absence of mosquitoes from the hut for ten days after treatment is more likely to be due to the repellent effect of a heavy dosage of kerosene than to the presence of DDT.

In the case of an isolated village, outside resting-places had been found and kept under observation for many months, 113 *A. melas* caught in these outside resting-places had a sporozoite rate of 2.7 per cent. During a period of five weeks after treatment of the village with DDT in kerosene (200 mgm DDT per sq ft), 295 blood-fed and gravid mosquitoes were caught in the outside resting-places, with a sporozoite rate of 2 per cent, infected mosquitoes were still found at the 5th week.

Conclusion

The sharp fall in house catches after treatment with DDT in kerosene does not necessarily mean a corresponding reduction in mosquito population or biting activity. The most obvious effect of the treatment is to bring about a

complete shift from indoor to outside resting places. Furthermore the sporozoite rate of those mosquitoes caught outside is such as to suggest that malaria transmission is still possible.

[This work rightly draws attention to the fallacies associated with the indiscriminate use of DDT in kerosene applied as a residual insecticide in West Africa. Health officers there might well infer that the residual insecticide method is valueless as a measure of malaria control. On the contrary the author's valuable paper should stimulate further investigation.]

Using Gammexane in kerosene in Sierra Leone DAVIDSON (this Bulletin 1948, v 45 157) produced evidence to show that the treatment of houses in part of an area reduces the mosquito population, not only in that part but also in adjacent parts one to two miles distant. The area concerned was a coastal strip six miles long, with a string of seven villages, of which the first, third and sixth were untreated. Similar results were obtained in a group of inland villages.]

BRAGA, E., PEXIDO H. M., BASSÊRES M. S., PINTO D. B., BEZERRA, F. P. Jr. & MOURA, F. P. *Malária no vale do rio Doce. Expurgo domiciliar com DDT em suspensão aquosa. 1 fase.* [Malaria in the Valley of the River Doce: Treatment of Habitations with Aqueous Suspension of DDT.] *Rev. Hig. e Saúde Pública* 1947 July-Sept., v 3 No 2 28-59 3 maps & 3 charts. 14 refs.

In September 1948 the DDT spraying of houses was commenced as an antimalaria measure along 120 kilometres of the Vitória-Minas Railway in the most malarious parts of the valleys of the River Doce and Itapicaba in the State of Minas Gerais (see above). The width of the area treated varied from 3 to 15 kilometres. The total area was about 1,500 square kilometres containing a population of about 20,000 in 5,000 houses. An aqueous suspension of DDT was applied (5 per cent) at the rate of 2 gm. per square metre. In January 1947 a second application was begun. About 85 per cent of all houses were treated. The almost complete absence of *L. darlingi* from houses treated, a marked fall in the number of malaria parasite carriers and a very notable fall in the number of persons applying for treatment for malaria, testify to the noteworthy success achieved. Very full details are given of the work carried out.

GRAMICCIA, G. & MCCA, G. *Not sulla infezione da *P. gallinaceum* nel pulcino. Considerazioni sul significato biologico del ciclo endosporocitario dopo inoculazione di sangue.* [Biological Significance of Exoerythrocytic Cycle of *P. gallinaceum* in Young Chicks.] *Ann. di Parasit. Rome* 1947 Dec. v 8, No 4 213-19. English summary.

The inoculation of young chicks 5-8 days old with blood infected with *P. gallinaceum* produces more severe infection than when adult chickens are

inoculated The young chicks first show exoerythrocytic forms on the 11th day of the blood infection, which is always fatal The author interprets this period of eleven days as a cycle wherein the parasite attempts to repeat those phases that were omitted because of the method of inoculation In the case of *P. elongatum*, blood inoculation is followed at the same time by both erythrocytic and exoerythrocytic development, while in the case of gametocytes these appear after a number of erythrocytic cycles

RIGDON, R H & McCAIN, B E Some Factors that Influence the Degree of Parasitemia in Ducks infected with *P. lophurae* *Amer J Trop Med* 1947, Nov, v 27, No 6, 673-81, 7 figs [19 refs]

Young ducks 2-4 weeks old, when given a lethal dose of *P. lophurae* die at the height of the parasitaemia or when the parasites are decreasing in number Some ducks, however, survive the infection, which may reach a figure of 400 infected cells per 500 red blood corpuscles on the 5th day of infection In the survivors, the number of parasites rapidly decreases, so that in 48 hours only 5-10 parasitized cells per 500 red blood corpuscles are present These ducks rapidly return to normal and within 5-7 days show no abnormalities in their haemogram It seems improbable that the cells of the reticulo-endothelial system which are filled with pigment at the crisis are able to remove from the circulation the large number of parasites then present

It has been shown that ducks with polycythaemia have larger numbers of parasites than normal ducks, while transfusion of infected ducks with normal red blood cells will prevent the decrease in the parasites which follows the peak of the infection Another factor which will increase the number of parasites is oxygen for ducks placed in a chamber with a concentration of oxygen of 30-80 per cent show a greater number of parasites in the peripheral blood Again *P. lophurae* prefers mature red blood cells to those that are young and there is a marked diminution of adult cells when the parasitaemia is high These young cells are poor in haemoglobin and the oxygen-carrying ability of the blood decreases during the infection

It has recently been shown that if blood for inoculation is treated with CO₂ by bubbling the gas through it, many of the parasites are so altered that it fails to produce the same degree of parasitaemia as when oxygen or nitrogen are bubbled through it Observations have shown that malaria-infected ducks develop a severe acidosis which is directly related to the anaemia The

CO₂ content of the plasma however remain approximately normal until the anaemia falls to below one million, after which it declines steadily till the time of death. After the administration of ammonium nitrate to ducks, there occurs a severe acidosis with no anaemia, while there is a decrease in the CO₂ content of the plasma. Administration of sodium bicarbonate is followed by a severe alkalosis with only slight anaemia and increase in the degree of retention of CO₂. It is concluded that the acidosis which occurs in malaria may not result entirely from the anaemia, since ducks with an acidosis following ammonium nitrate administration have no anaemia. To determine the relation of the total number of red cells to the CO₂ in the plasma, the CO₂ content was divided by the number of red cells in millions. This factor was plotted against the total number of red cells. A similar factor was obtained from ducks which had received ammonium nitrate and sodium bicarbonate. The points in the chart for the ducks with malaria parallel those of the ducks which had sodium bicarbonate. When the figure given by dividing the CO₂ content of the plasma is plotted against the number of parasitized red cells, it is found that the CO₂ content increases with the number of parasitized red cells. The greatest increase occurs when the parasitized cells number 250 or more per 500 red cells. It is thought that the CO₂ content may be sufficient to injure or kill some of the parasites.

TRY PANOSOMIASIS

HARDING R. D. & HUTCHINSON M. P. Sleeping Sickness of an Unusual Type in Sierra Leone and its Attempted Control. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1940, Jan. v 41 No 4 481-512, 1 map

In 1939 and 1940 medical surveys showed that sleeping sickness existed in an area of about 700 square miles on the eastern boundary of Sierra Leone adjoining French Guinea where the disease had been treated since 1934. Mass campaigns were decided on and were carried out in 1941-194 and 1944.

Sleeping sickness in Sierra Leone is caused by *Trypanosoma gambiense* and is spread by the bite of the tsetse fly *Glossina palpalis*. In the campaigns the basis was made by microscopical examination of the fluid obtained by puncture of enlarged superficial lymphatic glands and of blood films but as trypanosomes were found in the glands four times as often as in the blood, the latter was only examined when gland puncture gave negative results or when the glands were not palpable.

In 1941 the disease was clinically like that in other parts of Sierra Leone but in 1944, in the central part around the town of Freetown some differences were observed. Trypanosomes were found in the blood as often as in the glands and were unusually numerous in the blood. In some persons many patients had no enlarged cervical glands and showed no symptoms even when the blood contained many trypanosomes. All the inhabitants were examined and all cases of sleeping sickness were treated, but no further work was possible for a year. A survey in 1944 showed that the unusual form of the disease ("Freetown type") had spread considerably and the infection rate was nearly doubled. In Freetown itself, trypanosomes were found in the blood ten times as often as in the glands but in 1945 this disparity was less.

Seventy-five patients were left untreated and examined weekly for 6 months and 17 others, also untreated, were examined monthly for 7-9 months. Nearly all showed no symptoms or physical impairment. Trypanosomes appeared in the blood irregularly and it was reckoned that about 35 per cent. of cases would escape diagnosis at any single examination. Even patients with an increased

cell-count in the cerebrospinal fluid often had no symptoms. There seemed to be a state of equilibrium between host and parasite and some spontaneous recoveries probably occurred, but observation for several years would be required to confirm this. Although from a quarter to a third of the population of Fwero had been infected, the population had not decreased.

In experimentally infected monkeys the disease was also mild, in infected guinea-pigs the trypanosomes were resistant to intraperitoneal injections of human blood serum and sensitive to tryparsamide—characters of *T. gambiense* [Injection of human serum into guinea-pigs infected with *T. rhodesiense* will, in certain doses, banish the trypanosomes for several days].

Prophylaxis—The population (15,550) of the whole area received prophylactic injections of antrypol (germanin) or pentamidine isethionate and special observations were made of the 2,500 inhabitants of the central part, including Fwero, all the latter were examined by gland puncture and blood films and lumbar puncture was done in nearly all infected persons. Some of the sleeping sickness cases were fully treated, others left untreated, and still others received prophylactic doses of antrypol or pentamidine to see whether this would suppress the infection. A prophylactic injection was given to 1,765 uninfected persons and 542 were left as controls. The results with various prophylactic doses are shown in tables.

In infected persons given prophylactic doses, the blood showed no trypanosomes for at least 7 months, therefore missed cases of infection receiving a prophylactic dose would hardly infect tsetse flies during that period but their recognition later would be difficult and they might eventually become infective. No gland infections and only 2 blood infections were found after 7 months among 1,498 uninfected persons examined who had received prophylactic injections—a rate of 0.1 per cent—while among 471 controls there were 12 gland infections and 12 blood infections (5.1 per cent).

In two other areas of Sierra Leone, where sleeping sickness of the usual type was present, prophylactic injections proved very effective, after 1–2 grammes of antrypol, only 2 cases occurred among 772 people (0.26 per cent) and after 100–300 milligrammes of pentamidine no infection was found among 921 people while among 2,407 controls 22 cases (0.92 per cent) occurred. The period of observations in these investigations was 10 months.

The authors discuss the results and conclude that prophylaxis by drugs is more effective than treatment of cases in checking an epidemic and acts more quickly. Pentamidine is preferable to antrypol, being at least as efficient and having fewer undesirable side effects, a single intramuscular dose of 150 milligrammes is the best for a mass campaign. The importance of the possible masking of symptoms by prophylactic injections remains undecided.

J. F. Corson

GELFAND, M. **Transitory Neurological Signs in Sleeping Sickness** *Trans Roy Soc Trop Med & Hyg* 1947, Oct, v 41, No 2, 255–8

The author (writing from Salisbury, S. Rhodesia) discusses the usual symptoms and signs which indicate involvement of the nervous system in sleeping sickness, remarking that these are changes in personality rather than true neurological signs. This is to be expected in view of the fact that the disease is essentially a form of encephalitis, pathologically not unlike general paralysis of the insane. If paralyses do occur, they are usually not extensive, and the author has been unable to trace any record of transient paralyses in sleeping sickness. He now describes a case in an adult African, in which symptoms pointed to a form of encephalitis or tuberculous meningitis, with swelling of the right optic disc, a right extensor plantar response, and, shortly afterwards, a

right facial palsy which disappeared spontaneously in about 2 weeks. At this time no definite evidence of trypanosomiasis could be obtained, but about 6 weeks later the gradually worsening symptoms led to another examination of the spinal fluid, in which trypanosomes were now abundantly found. The type of disease was not definitely determined, but was probably *Rhodesia*. Treatment with trypanamide and pentamidine was successful, but the patient left hospital when the course was completed, and his later history is not known.

VAN HOOFF L. HENRIARD C. & PERL E. Notes sur l'action curative et préventive de la propamidine. [The Therapeutic and Prophylactic Action of Propamidine.] *Ann. Soc. Belge de Méd. Trop.* 1947 June 30 v 27 No. 2, 257-63.

The authors describe their experiences in the treatment of different types of sleeping sickness cases in Léopoldville. Propamidine (isethionate) was used in daily doses of 1 to 2 mgm. per kilo intramuscularly till a total of 45 mgm. per kilo was given. In 5 hospitalized patients thus treated in 1943 no relapse occurred. In one arsenic resistant case with a moderate increase in leucocytes in the cerebrospinal fluid a return to normal had not taken place at the time of writing and one non-arsenic resistant case did relapse. Further cases responded less well to treatment and trypanosomes disappeared but slowly from the peripheral blood. Immediate toxic effects from the drug were of minor importance but paralysis occurred later in some cases. Nervous symptoms appeared to be avoidable if the drug were given intramuscularly. The authors confirm the abortive action of the drug described below by EERAERTS. Prophylactic experiments on guinea-pigs with a single dose of propamidine gave similar results to those previously obtained by the authors with pentamidine (this *Bulletin*, 1944 v 41 928). In human cases, the protection afforded by 5 mgm. per kilo was estimated to last 6 months as with pentamidine. The two drugs thus appear to have comparable protective and curative properties against *T. gambiense* infections but propamidine seems to be more toxic, giving rise to paresis and paralysis.

J. D. Fulton

EERAERTS W. La propamidine comme préventif dans deux foyers de trypanosomiase humaine au Congo Belge. [Propamidine as a Preventive in Two Foci of Human Sleeping Sickness in the Belgian Congo.] *Ann. Soc. Belge de Méd. Trop.* 1947 June 30 v 27 No. 2, 201-24. [20 refs.]

The author refers to the earlier work of VAN HOOFF *et al.* (this *Bulletin* 1944 v 41 928 1948 v 43 536) on the value of pentamidine in prevention and treatment of Gambian sleeping sickness in the Belgian Congo. He himself has carried out comparable field trials with propamidine in two active foci of infection in the Kwango district of Léopoldville province. Two injections of the drug in 4 per cent. solution were given deeply into the muscles, with an interval of six months between doses. For adults the maximal dose was 5 mgm. per kilo (presumably of isethionate) with gradations according to age. In all, about 8 000 Africans were injected, none of whom was clinically ill. At the time of the first injection, the disease was spreading rapidly in one district. Examinations were made at intervals of 2 or 4 months after the injections and again at the end of six months, when no infection could be found in those who had received the drug. Four and nine months after the second injection the same state of affairs held. In a second focus of infection the trypanosomes were arsenic-resistant and the disease was spreading rapidly with 23.5 per cent. of new cases in a total of 41.1 per cent. of the population infected. Three and six

months after injection with propamidine, no fresh cases were present among those treated. From his experiments the author concluded that protection lasted from 6 to 8 months

The drug does not clear the peripheral blood rapidly and he considers its chief rôle to be that of a preventive rather than curative agent. There were some minor toxic symptoms from the drug, including epigastric pain, transient albuminuria and mild paresis of limbs. Two aged patients exhibited more serious signs of intoxication, including lowered blood-pressure, tachycardia, dyspnoea, severe epigastric pain and coma, but recovery was complete after 12 hours. The abortive action of propamidine has not previously been recorded since smaller doses of the drug have generally been used. The large dose of 5 mgm of propamidine per kilo, however, brought about this result in a large percentage of pregnant women. Half this dose was well tolerated.

The mechanism of the protection afforded by propamidine is not yet clear, but the practical achievement of wiping out one focus of infection and nearly eradicating another is of the utmost importance. The results compared favourably with those obtained by the use of Bayer 205, and advantages claimed for propamidine over Bayer 205 are its greater solubility and lesser toxicity, as well as the fact that it can be given intramuscularly

J D Fulton

WILLIAMSON, J & LOURIE, E M "Melarsen" and "Melarsen Oxide"
Nature 1948, Jan 17, 103-4 [14 refs]

VAN HOOF [this *Bulletin*, 1947, v 44, 1048] found that melarsen oxide, a new type of phenylarsenoxide containing a melamine group, was active against arsenic-resistant trypanosomes in the field. His findings have been confirmed by the present authors in the laboratory. They point out that arsenic resistance in the case of trypanosomes in fact involves resistance to the substituted phenyl group to which the arsenic is attached. It was recognized in the earliest investigations that trypanosomes made resistant to atoxyl failed to exhibit this property on treatment with aromatic arsenicals containing acidic groups. KING & STRANGEWAYS [this *Bulletin*, 1943, v 40, 20] suggested three ways in which the different types of aromatic arsenoxides may be distributed in or on the trypanosome, while the final reaction in which the parasite was killed probably involved in all cases combination between the arsenoxide and sulphhydryl groups in the trypanosomes. Interference experiments were used to provide evidence that melarsen oxide may combine with the trypanosome in still another way. Thus melamine itself and Surfen C, which also contains a melamine group, were found to interfere with the therapeutic action of melarsen oxide on a normal strain of *T. rhodesiense* as did *p*-aminobenzoic acid with that of γ -(*p*-arsenosophenyl) butyric acid and glutathione with arsenoxides in general. The authors conclude that the mode of combination between trypanosomes and melarsen oxide is different from that of other arsenoxides, although the final lethal effect of the latter is produced in the same way. The interference between melarsen oxide and Surfen C appears to depend on the common possession of a melamine group

VANDERPLANK, F L Seasonal and Annual Variation in the Incidence of Trypanosomiasis in Game *Ann Trop Med & Parasit* 1947, Dec, v 41, Nos 3/4, 365-74 [15 refs]

These investigations were made in Tanganyika Territory from June 1939 to June 1944, 378 wild mammals belonging to 38 species were shot and their blood examined microscopically for the presence of trypanosomes. The results

In 135 of them (153 in the text) were recorded in a previous paper (*Trans. R. Soc. Trop. Med. & Hyg.* 1942, v 35 319). Similar observations by E. F. THOMSON in Northern Rhodesia are also shown in a table.

Giraffes showed the highest rate of infection (37 per cent.) then roan, eland, zebra, impala and wart-hog in that order while no trypanosomes were found in carnivores, monkeys and rodents. *Trypanosoma congolense* (*T. sinensis*?) was found in 1 of 6 elephants. There were no significant differences in the rates of infection between young and adult animals nor between the sexes. The rate varied with the season, being highest in March and April, the time of heavy rain, and it varied also from year to year in correlation with annual variation in the proportion of infected wild tsetse flies. The animals were far more often infected with *T. congolense* and *T. vivax* than with *T. brucei*, the rate of the last being less than 1 per cent.

Wild tsetse flies, *Glossina morsitans* and *G. pallidipes* were dissected and examined and the following rates of infection with trypanosomes were found among 33 112 flies: *T. congolense* 2.2 per cent., *T. vivax* 2.1 per cent. and *T. brucei* less than 0.1 per cent. The author found (unpublished work) that temperature markedly affected the transmissibility of *T. rhodesiensis* and *T. congolense*. The activity and hunger cycle of tsetse flies and their apparent and actual numbers were also investigated.

The erythrocytes of blood recently imbibed by 1,600 *G. morsitans* were measured and the results indicated that this species feeds largely on giraffes and large antelopes, some observations by the author (this *Bulletin*, 1944 v 41 1010) showed that *G. pallidipes* preferred to feed on pigs.

Various species of wild animals were experimentally infected with *T. rhodesiensis*; wart hogs rarely showed trypanosomes in the blood, but rats were infected from them by inoculation. Trypanosomes appeared in the blood of elands for several days at a time up to 6 months after the infecting bite and a goat was infected by inoculation of 50 cc. of blood from an eland infected as previously. Other animals showed various degrees of infection. J. F. CORRIE.

WILDE, J. K. H. The Maintenance of Cattle under Conditions of Tsetse Fly Infestation in the Field. *J. Comp. Path. & Therap.* 1947 Oct., v 57 No. 4 294-300. 1 sketch map.

This experiment was made to see whether cattle could be kept in good health by the use of drugs in a district in Tanganyika Territory where clearing work to get rid of tsetse flies was in progress, but would not be able to eliminate the flies for a long time. It also served to test the value of two drugs—No. 897 (a compound of phenanthridinium chloride) and Stibophen (antimony). The experiment began in September 1944 and lasted for 14 months.

A number of cattle (153) were divided into 5 herds (A, B, C, D & E) which were then stationed at 4 different places respectively in the area. Their blood was examined microscopically every fortnight for trypanosomes and the drugs were used prophylactically and to treat infections. In herd A (11) infected animals received Stibophen twice with a week interval between the doses. In herd B (31) infected animals received one dose of No. 897. Herd C was subdivided into groups a, b and c for treatment but all were kept together. In a (15) all got Stibophen once a month. In b (16) all got No. 897 once a month, and in c (15) infected animals got No. 897 after each fortnightly post-mortem blood film. In herds D (25) and E (40) No. 897 was given each when a blood film was positive.

Infections were arbitrarily called new as distinguished from relapses, if a positive blood film had been preceded by two fortnightly negative films.

female mice as judged by trypanosome population in the blood, degree of tissue infection, loss of body weight and survival of the host. C. M. Weyen

MUNIZ, J. & DE AZEVEDO, A. P. Novo conceito da patogenia da "doença de Chagas" ("Trypanosomiasis Americana"). Inflamação alérgica granulomatóide (A) e miocardite hiperérgica (B) produzidas em Rhesus ("Macaca mullata") inoculados com formas mortas de cultivo do "Schizotrypanum cruzi" (Nota prévia.) [New Conception of the Pathogenicity of Chagas's Disease.] Hospital Rio de Janeiro, 1947 Aug. v. 32, No. 2, 165-83 8 figs. [22 refs.] English summary

The authors have studied the pathogenicity of *Trypanosoma cruzi* by sensitizing two monkeys by intravenous injections of a protein-free antigen and then administering a shock injection. The antigen was prepared from cultures grown on solid medium. After the flagellates were washed with saline solution they were dried at a temperature of -70°C . They were kept dry at a temperature of -10°C . or in suspension in distilled water.

To carry out the test, two rhesus monkeys received five intravenous injections of the antigen at intervals of 3 days, two of the injections being 0.040 gm. and three 0.045 gm. Twelve days after the last injection, a shock injection of 0.010 gm. of antigen was given directly into the pleura and the cardiac region. One of the animals was given three further injections of the sensitizing antigen. One of the monkeys was killed eight days after the shock injection and the other 33 days after. Before being sacrificed, both monkeys gave ++++ precipitin reaction according to the method of Muniz and Freitas. As controls, two monkeys were given injections of antigen without a shock injection.

Examination of the pleura and cardiac tissues of the monkeys showed that inflammatory reactions were set up, there being a similarity of the histopathological picture to the lesions in Chagas's disease. In the control monkeys, such lesions did not occur. The experimental result supports the conclusion of TORRES that there is an allergic condition in the pathogenesis of the disease.

C. M. Weyen

VALLS, D. J. Contribuciones al estudio de la enfermedad de Chagas. VI. Estudio cardio-vascular de enfermos de trypanosomiasis Americana. [Chagas's Disease. Cardiovascular Study.] Rev. Chilena de Hig. y Med. Preventiva, 1947 June v. 9 No. 2, 189-249 7 figs. on 8 pls. [53 refs.]

In this study the author first carried out xenodiagnostic tests—any persons found positive were then examined clinically to exclude those with other common causes of cardiac disturbance—valvular lesions, arterial hypertension, hyperthyroidism, etc. The districts where the examinations were carried out were rural and heavily infested with *Triatomidae*.

The author analysed 411 cases—so stated repeatedly—but in a table giving the age and sex of the patients the total should be 417—the numbers of males in one district, San Enrique, being wrongly added and in another column the age distribution total is again wrong. Of 397 electrocardiograms, there were 123 with sinus arrhythmia, 11 with A-V block 8 with ventricular extrasystole (most of these patients were young—4 18 years of age) and 5 with auricular extrasystole. In spite of this, there seemed to be little if any general disturbance of health or limitation of capacity to work. Details are given of 18 cases and in an appendix a general scheme is laid down for clinical study of Chagas's disease noting the points to be looked for and the various laboratory tests to be carried out (xenodiagnosis, Machado reactions, etc.) autopsies should be made when permitted, otherwise necropsy samples should be taken.

H. Harland Smith

AUGUSTINE, D L Experimental Studies on Trypanosomiasis (*Trypanosoma lewisi*) *Liber Jubilans J Rodham* (Soc Belge Méd Trop, Brussels) 1947, Dec, 63-80, 3 figs

The substance of this paper appeared in an earlier publication by the author [this *Bulletin*, 1946, v 43, 1025] C M Wenyon

CALDWELL, F E & GYÖRGY, P The Influence of Biotin Deficiency on the Course of Infection with *Trypanosoma lewisi* in the Albino Rat *J Infect Dis* 1947, Nov-Dec, v 81, No 3, 197-208, 1 fig [25 refs]

It has been shown by various workers [this *Bulletin*, 1943, v 40, 825, 891, 1944, v 41, 651, 1945, v 42, 540, 864] that the course of a protozoan infection may be modified by deficiency of certain vitamins in the host. The effect of biotin deficiency on the course of *T lewisi* infection in rats has now been further investigated by the present authors. To produce this deficiency, one group of animals was given a modified egg-white diet supplemented by other vitamins. Another group received a linoleic acid diet involving a toxic factor and a low protein intake which was also supplemented by other vitamins and did not increase susceptibility to *T lewisi* infection. The degree of biotin deficiency was assessed from the appearance of the animals. A standard number of trypanosomes, based on body weight, was used for inoculation. Red cell as well as parasite counts were made regularly up to some days after the disappearance of parasites. Death from bacterial and other causes was common in the deficient groups, and all had more severe infections than the controls, while death from very intense infections occurred in moderately deficient rats. When adequate amounts of biotin were given subcutaneously to the latter, the development of trypanosomes was not immediately controlled. Excess biotin given to normal rats likewise exerted no protective or curative action. Treatment with hyperimmune serum caused the trypanosomes to disappear within 24 hours in non-deficient rats, but not in the deficient rats, which later succumbed to the infection. A deficiency of complement in their serum was indicated. The results suggest that biotin deficiency caused delayed and diminished production of ablastin as well as of trypanolysin, so that an intense and prolonged infection resulted. J D Fulton

DEANE, Maria P Ocorrência do *Trypanosoma conorrhini* em "barbeiros" e em rato na cidade de Belém, Pará, e seu cultivo em meio de NNN [Occurrence of *Trypanosoma conorrhini* in "Kissing-Bugs" and a Rat in Belém, Pará, and its Cultivation on NNN Medium] *Rev Serviço Especial de Saúde Pública* Rio de Janeiro 1947, July, v 1, No 2, 433-48, 70 figs on 6 pls English summary

The "kissing-bugs" in question, which were found in houses in the "Cidade Velha" section of Belém, Brazil, were identified as *Triatoma rubrofasciata*. Faecal material from the insects revealed the presence of a trypanosome which was proved, by inoculation of white mice to be *T conorrhini*. The same infection was found by xenodiagnosis in a live rat caught in a house infested with the infected bugs, although no trypanosomes were found in fresh blood preparations from the rat. In addition to trypanosomes in faecal material of bugs which had fed on the rat, typical trypanosomes were also found in the blood of mice infected by inoculation of such material.

Trypanosoma conorrhini was cultured readily on NNN medium from the blood of laboratory-infected mice and rats and from the naturally infected rat, even when direct examination of the blood was negative.

The author points out that as *Triatoma rubicula* and other *Triatomidae* are frequently infected naturally with *Trypanosoma concolor*, this fact should be kept in mind, by those working on Chagas's disease, preferably when xenodiagnosis is being performed on wild or domestic animals, or the search for *Trypanosoma cruzi*. Laboratory animals should be inoculated with the flagellates found in the intestines of the bugs so that the blood parasites might be identified with certainty.

LEISHMANIASIS

DORE, G. Maria. Contributo alla conoscenza della leishmaniosi in Sardegna. [Observations on Leishmaniasis in Sardinia.] *Pediatrics*. 1947 55 Nov. 13 108-15. [74 refs.] English summary (3 lines).

MOXIMINI E. M. La leishmaniosi interna della Provincia di Palermo. Iulor-tatu: uno linee considerazioni sulla terapia. [Visceral Leishmaniasis in the Province of Palermo. Clinical Incidence and Observations on Treatment.] *Pediatrics*. 1940 July v. 48 No. 7 465-9.

GRIDEANI G. Sulla diffusione della leishmaniosi viscerale infantile nell'Arcipelago Toscano (8 casi osservati negli anni 1945-46). [Infantile Kala Azar in the Tuscan Archipelago. *Acta Med. Italica*. 1947 Oct. v. 2, No. 10 330-33. 10 refs.] English summary (4 lines).

The author describes eight cases of infantile kala azar which he observed in the hospital of Portoferraio during 1945-6. Seven of these were from the Island of Elba and one from the Island of Pianosa.

C. M. Hearn

GATTO I. Lo splenogramma nel kala-azar nostrano. [The Splenogram in Infantile Kala Azar. *Settimana Med.* 1946 Sept. 7 28 Year 34 n.s. v. 2, Nos. 38-39 105-12. 1 fig. [16 refs.]

The study of spleen smears from 28 cases of infantile kala azar has revealed the following cell types:

Haemohistioblastic cells divisible into indifferent haemohistioblasts and lymphoid or haematic haemohistioblasts; plasma cells; monocytic cells, divisible into histiocytoblasts, lymphoid and haemocyto-blastic cells; lymphocytic cells; medullar cells divisible into granuloblastic and erythroblastic cells. The origin of these various cells from one original splenoblast is shown in the form of a tree. The variations in the occurrence are discussed and the changes undergone by them during treatment are noted. The differential count before and during treatment are given in two tables. The various cell types are illustrated in a series of photomicrograms.

MURANO G. La splenomegalia leishmaniotica nel quadro delle sindromi bantiene. [Leishmanial Splenomegaly in the Banti Syndrome.] *Pediatrics*. 1944-45 v. 5, 53 1-52, 1 chart & 5 figs. [77 refs.]

In this article the author describes a fatal case of infantile kala azar in which the post mortem appearances showing curbing of the liver and spleen are suggestive of Banti's disease. He discusses various observations which have been made and concludes that leishmaniasis is one of the factors which may produce the Banti syndrome.

C. M. Hearn

- MURANO, G Polipeptidemia ed azotemia nella leishmaniosi interna [Poly-peptidaemia and Azotaemia in Visceral Leishmaniasis] *Pediatrics* 1941 Dec v 49, No 12 636-53 [38 refs]

- CARNEVALE, A Sull'importanza dei fenomeni interferenziali nell'associazione lue-leishmaniosi [Syphills obstructing Treatment of Kala Azar] *Pediatrics* 1943, May, v 51, No 5, 145-55 [22 refs]

In describing four cases of infantile kala azar which resisted treatment with tartar emetic, the author noted that there was a concomitant syphilitic infection. Response to tartar emetic was only obtained after a course of treatment for syphilis had been completed. He considers that a syphilitic infection should be suspected in all cases of kala azar which resist antimony treatment.

- MONTOYA, J A, OSEJO, P P & TOPPING, N H Typhus in Colombia a Survey of Four Towns by the Complement Fixation Test, November 1946 *Am J Trop Med* 1948, Jan, v 28, No 1, 163-71, 1 fig [10 refs]

The authors employed a complement-fixation test, in which *Rickettsia prowazekii* was used as the antigen, in a study of the sera of 966 persons between the ages of 5 and 49 years in four villages of South Colombia. The villages were about 3,000 metres above sea level, the average air temperature was about 11-12°C and the conditions of life were suitable in all respects for the maintenance of louse-borne typhus infection.

About 25 per cent of the sera gave positive reactions at titres of 1-8 or more and it was concluded that at least as great a percentage of the inhabitants had been attacked at some time with typhus fever.

The antigen used was not purified so as to differentiate between louse-borne and flea-borne typhus, but the epidemiological conditions described in the paper strongly suggest that the infection was louse-borne.

It is stated that there was no clear evidence that age or sex caused a statistically significant difference in the incidence of the disease, and that the incidence rates did not show peaks which could be considered as due to the occurrence of epidemics.

Kowicz, J. Techniques for Rickettsial and Virus Cultivation. *Proc. Soc. Exper Biol & Med* 1947 Oct., v. 68 No. 1 188-7

The technique described refers to the rearing of human body lice in sterile conditions for use in feeding experiments on patients suspected of being infected with virus and rickettsial diseases. Freshly hatched larvae, reared from eggs laid by laboratory bred lice which have to be fed twice daily on healthy persons, are fed on the patient in aseptic conditions twice daily for 4 to 12 days; the infecting organisms are sought in stained smears of the faeces and guts of the insects. Details of the technique are given.

The author states that he has "isolated and observed the infectious bodies responsible for a number of virus and rickettsiae-like diseases". The bodies are said to have been, for the most part round disks about the size of typhus rickettsiae and to have been causally associated with several diseases of a rheumatic type including acute rheumatism and chorea minor. In one case the disease was a toxic diarrhoea in an infant.

Larval bedbugs were reared in the same way and in some cases gave better results than louse larvae.

[It seems strange that the bodies seen in virus diseases should have been similar to those observed in rickettsial infections. The information supplied with regard to the practical application of the method of investigation is tantalizingly meagre. It is to be hoped that this aspect of the study will be dealt with in further communications.]

The early part of the investigation was carried out in the Weigl Typhus Institute at Lwow.]

John W. D. Megee

Giroud P. Pouvoir neutralisant de la streptomycine sur les Rickettsies du typhus épidémique mis en évidence dans la peau. [The Neutralizing Effect of Streptomycin on Rickettsiae of Epidemic Typhus as shown by Skin Tests.] *C. R. Soc. Biol* 1947 Nov. v. 141 Nos 21 22, 1117 19 4 charts

The author studied the effect of streptomycin on rickettsiae of epidemic typhus by intranasal inoculation of mice and by skin tests on rabbits. In the former experiments, 20 anaesthetized mice received 6 drops of a rickettsial suspension and thereafter were given 2,000 units of streptomycin daily. In some cases, 10,000 units were injected on the first day. In a first series of experiments, no rickettsiae were found in the lungs of the treated mice. In a second series, rickettsiae were found in approximately equal degrees in lungs of treated and untreated mice alike. However in the case of the treated animals, the rickettsiae often stained less readily, took a blue instead of a red colour with Macchiavello's stain and were punctiform. In the control mice the morphology and staining of the rickettsiae were normal. Evidently the only action of the streptomycin on the rickettsiae was to modify their morphology.

In the skin tests, the skin of rabbits was inoculated with 1 mgm. 2 mgm. and 4 mgm. of lung tissue heavily infected with rickettsiae mixed with solutions of streptomycin containing from 1.8 units to 18,000 units. The suspensions and the dilutions of streptomycin were kept in contact for 1 hour at 30°C. Neutralization of the rickettsiae was assessed in terms of the delay or feebleness of the local reactions produced. A chart and a table in the text indicate that 1,800 and 18,000 units completely neutralized the rickettsiae up to the 4 mgm. quantities of infected tissue; the smaller doses had a correspondingly weaker effect and 1.8 units only neutralized 1 mgm. completely while 1.8 units had little effect.

The author concludes that streptomycin has a definite effect on typhus rickettsiae when tested intradermally, but this is less in evidence in the case of experimental pulmonary infection

TUNA, I Yerli ve yabancı tífüs aşılarının muafiyet kudretlerinin karşılıklı mukayeseleri [Comparison between the Antigenic Power of Typhus Vaccines prepared in Turkey and elsewhere] *Türk İhyen Tecrübî Biyoloji Dergisi* Istanbul 1945, v 5, 107-14 [18 refs] French summary

In the author's laboratory at the Central Institute of Hygiene in Refik Saydam, typhus vaccine was prepared during the war by the cultivation of rickettsiae in the egg embryo (Cox). In the present investigation, the antigenic power of this vaccine was compared in guinea-pigs under carefully controlled conditions with vaccines from seven other prominent sources in Europe and the United States. The results are tabulated, and although not more than 10 guinea-pigs were used in any one test, it is claimed that the Refik Saydam vaccine was as active as the others, on the basis of the number of guinea-pigs successfully immunized with it

COLE, L C & KOEPKE, Jean A Problems of Interpretation of the Data of Rodent-Ectoparasite Surveys and Studies of Rodent Ectoparasites in Honolulu, T H., Savannah, Ga., and Dothan, Ala *Supplement No 202 to Pub Health Rep* Wash 1947, 71 pp 3 figs & 3 maps [63 refs]

In the first part of this report, the authors discuss the complexities to be considered in applying the "flea-count" technique to investigations into the populations of rodent ectoparasites. The chief object of such surveys being to obtain an index from the raw data which will bear an approximate relationship to the total ectoparasite population sampled, it is essential that several factors which complicate such studies should be borne in mind.

Some of the points discussed include the accurate identification of species of ectoparasites and their hosts, their sex and age, food of the host, location of traps, number of traps, number of rats per trap, efficiency of the traps and of the trappers, and many more. The meaning and limitations of different types of indices are considered, in particular, the mean number of fleas per rat, mean *Xenopsylla cheopis* per rat, mean female *cheopis* per rat and corresponding indices for infested rats. The mean number of female *cheopis* per infested rat is probably the most promising of these indices for evaluating the effect of control measures, because normally it is the least variable, but the reader is warned that this index cannot yet be justified for use with other species.

It is pointed out that in different places, different factors may take precedence in influencing the index. The survival of fleas away from their hosts is promoted by low temperature and ample moisture, but a high temperature induces more frequent feeding and increases the proportion of males in the catches. However as the value of the vector-count technique seems to have been established it may perhaps merit extension into other fields of enquiry. For instance, it may be found that vector indices correlate more closely with enzootic typhus than with human typhus and more closely with the microclimate of the rat-holes than with data from weather stations, but these are subjects for special investigation and are not measurable from the data available in these reports.

The results of a survey of rodent-ectoparasites of Honolulu are then considered. Trapping of rodents began in January 1934 and ended in January 1935. Results for 282 days catches are analysed. Of 6 664 rats, 4,967 (74.5 per cent) were

Rattus norvegicus 1,238 (18.8 per cent.) were *R. rattus* and 459 (6.9 per cent.) were *R. argentensis*. The fleas from 6,382 of these rats numbered 414⁰⁰. *Echidnophaga gallinacea* formed over 59 per cent. and *Yemophilus albus* over 39 per cent. other fleas taken were *Cimexopsyllodes felis* and *Y. hawaiiensis*. The number of mites taken from 603 rats (a 10 per cent. sample) was 8,931 among them *Laelaps karwinskii* accounted for over 91 per cent. *Echidnophaga echidnina* 8 per cent. and *Liponyssus bacoti* 0.4 per cent. Lice from the sample 603 rats were 2,380 and of these *Polyplax spinulosa* amounted to over 82 per cent. and *H. papillipes* spp. to over 17 per cent.

The figures are analysed in a dozen tables and from these it is seen that *R. argentensis* had significantly fewer lice and fleas than *R. rattus* and the latter had fewer fleas than *R. norvegicus*. Mites occurred indiscriminately on the different rats. The mite *L. karwinskii* was abundant in the wet season and the flea *Y. cheopis* was most prevalent in the dry season. Certain aspects of these results seem to warrant further careful investigation, for the mite *L. karwinskii* was apparently more abundant than the flea *Y. cheopis* and the mite *L. bacoti* (a laboratory vector of rodent typhus) was comparatively rare moreover the survey shows that human incidence of typhus coincided more closely with the peak abundance of *L. karwinskii* than with that of *Y. cheopis*. These findings demonstrate the necessity for ectoparasite surveys in different places, at different times and under a variety of conditions.

The results of similar work in Savannah, Georgia, are next analysed in the same way except that all rats (rather than a 10 per cent. sample) are included in the examination for mites and lice as well as for fleas. Trapping was done from January 1932 to December 1933 during 817 trapping days. Here *R. norvegicus* formed over 90 per cent. of the total rat collection (7,813 rats) while less than 7 per cent. were *R. rattus*. The situation here appears to be even more complex because though Savannah is regarded as a city with a relatively high incidence of endemic typhus, this is not associated with any peculiar qualitative features disclosed by the analysis of the survey figures. The mite *L. bacoti* while more abundant here than in other cities surveyed (33,496 or 45 per cent.) failed to show the seasonal variations characteristic of this disease. The data for Savannah offer little information except that important ectoparasites were found. These were those named above with the addition of *Leptopsyllus segnis* (a flea which was more closely associated with *R. rattus* than with *R. norvegicus*) and some other less abundant species.

The last part of the report deals with surveys at Dothan, Alabama, which is not a seaport. Rat collections were made from March 1933 to March 1934, during 317 trapping days. The figures analysed are those from 4,833 rats, of which *R. norvegicus* made up about 63 per cent. and *R. rattus* 0.7 per cent. Of 51,005 fleas *Y. cheopis* accounted for over 48 per cent. *E. gallinacea* over 29 per cent. and *L. segnis* over 21 per cent. Of 15,231 mites, *E. echidnina* was easily the commonest, with over 91 per cent. and of the lice (8,900) over 93 per cent. were *Polyplax spinulosa*.

The results from the Dothan survey contrast with the results from other places. The area is one of high incidence of endemic typhus, and because of the low figures for *R. rattus* (45) and the mite *L. karwinskii* (8) neither of which appear to be essential for transmission and because *P. spinulosa* and *E. gallinacea* though numerically adequate show variations inconsistent with typhus epidemiology suspicion is therefore directed to *Y. cheopis*.

BERTAZZI, C G Ulteriore contributo alla terapia del dermatifo murino della Sicilia orientale mediante l'uso del chinino e della maretina [The Treatment of Murine Typhus in Sicily with Quinine and Maretine] *Acta Med Italica* 1947, Dec, v 2, No 12, 383-6 2 charts English summary

An account of two cases with apparently good results

WILEY, J S A Preliminary Report concerning DDT Dusting and Murine Typhus Fever in Nine South-eastern States *Pub Health Rep Wash* 1948, Jan 9, v 63, No 2, 41-3, 1 fig

In July, 1945, the U S Public Health Service inaugurated a typhus control programme in 9 south-eastern States, in collaboration with the State Health Departments The work was continued throughout 1946 and the first half of 1947 The programme involved primarily the application of 10 per cent DDT dust to rat runs, burrows and harbourages in an attempt to reduce rat fleas and other ectoparasites and so to control human murine typhus fever

This work was carried out in 122 of the highest typhus reporting counties in the 9 States, which between them had accounted in 1944 for 72.3 per cent of all typhus reported in these "typhus" States or 70.5 per cent of all typhus reported in the entire U S A

A table and a figure show the results of these dusting operations, tabulating separately the figures from the 122 counties which operated the dusting projects and those from the 460 counties which did not The year 1944 is also shown as a "precontrol" year

These results show that in the period July-December 1945 a decrease in reported typhus of 10.7 per cent occurred in dusted counties compared to an increase of 14.5 per cent in the non-dusted counties, a differential of 25.2 per cent In 1946 and half of 1947 the differentials were 44.1 per cent and 56.4 per cent

The reported cases decreased in the 10 highest "typhus" counties from 1,074 in 1944 to 395 in 1946 In tabulating the results, DDT dusting is the only control measure taken into account

In the treated areas, flea counts from some 17,000 live rats have indicated that *X. cheopis* reduction has averaged 84 per cent

H J O'D Burke-Gaffney

BETTINARDI, G La febbre esantematica mediterranea [Mediterranean Exanthematic Fever] *Pediatria* 1942, Sept, v 50, No 9, 343-52

The author presents a critical summary of the extensive literature connected with the tick-borne typhus fever which occurs in the countries round the Mediterranean Sea, and which has been described under such names as bouton-neuse fever, escharo nodular fever, eruptive Mediterranean fever, Carducci's disease, benign "non-diffusible" dermo-typhus Marseilles fever, etc

The paper contains much information that will be found useful by students of the typhus fevers though some of the author's statements may be misleading to the uninitiated reader, for example, flea-borne typhus is constantly referred to as Brill's disease Stress is rightly laid on the doubt that exists as to whether all the cases described as belonging to the Mediterranean exanthematic fever sub-group have been correctly diagnosed, neither the Weil-Felix reaction nor the response of guinea-pigs to inoculation can always be relied on to differentiate the disease from murine typhus

In clinical diagnosis special importance is attached to the rash, which in most cases appears between the 2nd and 4th day, and when fully developed consists

of discrete papules, or even nodules (and tends to be widely distributed) extending to the face, palms and soles. Constanzi is quoted as saying that an eschar occurs in 30 per cent. of the cases.

PHILIP C. B. Comments on the Name of the Q Fever Organism. *Pub. Health Rep. Wash.* 1948 Jan. 9 v. 63 No. 2 58.

In this brief note the author produces arguments to support the use of the name *Coxsackia* for the aetiological agent of Q fever *R. burnetii*. He has been using the name as a full genus for teaching and other purposes during the war. "It is here proposed to validate that usage by elevating *Coxsackia* to the status of a full genus the genotype, of course, remaining the same i.e. *R. burnetii* Derrick, which now becomes *Coxsackia burnetii* (Derrick).

H. J. O'D. Burke-Gaffney

SMADAL, J. E., SNYDER, M. J. & ROBBINS, F. C. Vaccination against Q Fever. *Amer. J. Hyg.* 1948 Jan., v. 47 No. 1 71-81 1 fig. [22 refs.]

The authors working at the U.S.A. Army Medical Centre at Washington, D.C., prepared vaccines from yolk sac cultures of an Italian (Henszlering) and an American (Dyer) strain of *Rickettsia burnetii*. A concise description is given of the methods employed in preparing and testing the vaccines.

Guinea pigs inoculated with either of the strains of vaccine showed a rapid rise in the complement fixation titre for the Italian strain of antigen, starting about two weeks after inoculation but the rise in the titre for the American strain of antigen did not occur till about four weeks after inoculation. After about eight weeks the titres for both strains of antigen were approximately equal.

Guinea pigs that were already positive for the Italian strain, but had not become positive for the American strain, appeared to have acquired the same high degree of relative immunity against both strains of infection as was shown by the guinea pigs positive for both strains of antigen.

Among 28 volunteers inoculated with the Italian strain of vaccine 23 gave complement fixation titres of 1:20 or more when tested two weeks later with Italian antigen but all were negative to tests with American antigen.

Among 11 volunteers inoculated with the American strain of vaccine seven reacted at 1:20 or more to tests with the Italian antigen but only one reacted with the American antigen.

By later tests it was found that few of the volunteers ever developed complement fixing antibodies for the American strain and that only two failed to develop antibodies for the Italian strain though in a few cases the titres were only 1:5 or 1:10.

There was no opportunity for testing the efficacy of the vaccines against human infection.

YELLOW FEVER

KIRK, R. Eradication of *Aedes aegypti* in Khartoum. [Correspondence.] *Vaccine*, 1948 Jan. 24 129.

The author writing from the Stack Medical Research Laboratories, Khartoum, refers to an editorial note in *Vaccine* 1947 August 9th 188 in which it is stated that yellow fever has been eradicated from Khartoum "result of mosquito control measures". He points out that while *Aedes aegypti* has been

virtually eliminated in Khartoum, there is in fact no evidence of actual yellow fever infection ever having been identified there. Khartoum is north of the local yellow fever endemic area and immunity surveys show no evidence of infection having occurred during the life-time of the present inhabitants.

Since the successful anti-mosquito campaigns of BALFOUR some forty years ago, the mosquito situation in Khartoum has been observed constantly. records over that period suggest that *A. aegypti* has never been very abundant in that desert neighbourhood and has been eradicated, to reappear infrequently and be rapidly destroyed. Such reappearances in the past were probably re-importations, since the mosquito at one time was regularly brought to Khartoum by river steamers but the great reduction of mosquitoes on steamers is one of the effects of the present mosquito control measures in the Sudan described by LEWIS [this *Bulletin*, 1947, v 44, 656] whose paper was the subject of the editorial note referred to above. *A. aegypti* has not been reported on those steamers for several years.

PLAGUE

WANSON, M, RICHARD, P & TOUBAC, M. Les rongeurs et insectivores de Léopoldville et leurs ectoparasites [Rodents and Insectivores of Leopoldville and their Ectoparasites] *Rec Travaux Sci Méd Congo Belge* 1947, July, No 6, 3-38, 8 figs, 1 chart & 24 photos [50 refs]

A list is given of the names of 7 species of *Insectivora* and 26 *Rodentia* found in the Léopoldville area of the Belgian Congo. Among 29,245 domestic rodents examined, no specimen of the brown rat (*Rattus norvegicus*) was seen, but there were four forms of the black rat, namely *R. rattus* (1,772), *R. alexandrinus* (14,607), *R. frugivorus* (12,854) and *R. wroughtoni* (112). Among 10,461 non-domestic rodents taken outside the town, 22 species were represented, the commonest being the marsh rat *Dasymys benileyae* (5,689).

Descriptions are given of the animals, their burrows and their nests and a key is provided for their identification. There are also drawings and photographs of certain diagnostic characters, but, unfortunately, some of the names under the photographs of skulls have been misplaced and it has been necessary to insert a correction sheet in the volume.

Among the fleas taken from the domestic rodents, *Xenopsylla brasiliensis* was most common, being taken 29,008 times, *X. cheopis* was collected 13,816 times, *Ctenocephalides felis strongylus* 242 and *Echinophaga gallinacea* 158 times, maximum numbers were collected in the cool, dry months of August and September. The two species of *Xenopsylla*, though abundant on the rats, were rarely seen in houses. In African huts, *C. felis strongylus* and *Tunga penetrans* were common. *Polyplax spinulosa* was the only louse on the four black rats, though no numbers are given. In the dry season, the mites *Dermanyssus muris* and *Liponyssus bacoti* appeared on *R. alexandrinus*, from 600 rats, 210 *L. bacoti* were taken, the first time this mite has been identified from the Congo. Species of *Laelaps* also occurred, but only averaged 8 mites per 1,000 rats. Nymphs and adults of the tick *Haemaphysalis leachi* were collected but the numbers are not stated.

On 10,409 field and woodland rodents, 80 per cent carried mites, 1 per cent fleas and 19 per cent were free of ectoparasites. The fleas were *X. nubicus*, *X. brasiliensis* and *X. cheopis*, fleas of other genera were absent. Mites of the genus *Laelaps* were common, especially on some specimens of the marsh rat (*D. benileyae*), which were free of fleas. A few *H. leachi* were obtained and

some *Rhipicephalus simus* and *R. sanguineus*. At the mouth of the berr-
Phlebotomus schweileri *P. africanus* *Mansonioides africanus* *M. uniformis* and
Culex fatiga were taken on oiled paper traps. H S Lorton

ERZIN N & PATEL S. Akçakale verbası. (Plague in Akçakale.) *Türk
 İygen Tercübi Bıvıvıvı Dergisi* Ankara. 1947 1 7 No 3, 31-44. figs.
 & 1 folding chart. English summary.

In March-April 1947 19 cases of plague occurred in Akçakale Turkey.
 14 were axillary bubonic and 5 were septicæmic. Plague serum from the
 Pasteur Institute (80 cc daily) was not satisfactory but sulphadiazines proved
 of great value in treatment. In some cases these drugs were combined with
 serum therapy.

Serum and sulphadiazine were given prophylactically to 8 relatives of patients.
 they did not develop the disease but four persons who refused this treatment
 developed typical bubonic plague. As an insecticide 6 per cent DDT in
 petrol was very satisfactory. H J O'D Burke-Jones

FALST E C. Plague in the Americas. *Liber J. bilis J. Radham* (San. Bıvıvı
İfıd Trop. Bıvıvıvı) 1947 Dec. 213-24 2 figs. (maps). [17 refs.]

Plague in the Americas has been well reviewed in a large number of
 publications and the history of its introduction to the American continent in
 1899 by the Dutch ship *Zee* should be well known. In this article there is
 reference to the accepted view of how plague became established in ground
 squirrels. The San Francisco disaster of 1906 resulted in the escape of city
 rats from the Chinese shuns into the hills and the transference of their fleas to
 the squirrels. In continuation of this explanation there comes the author's
 view that it can never be proved that this so-called Asiatic plague did
 not exist prior to the San Francisco earthquake and even before the introduction
 of rat plague from China. Could this be comparable to the existence of
 endemic plague in the Kumaon hills of British India before its arrival at Bombay
 from Hong Kong. The author considers that plague exclusively in domestic
 rats could be eradicated but that the danger remains of reintroduction to the
 rat population of the infection from the enzootic plague of wild rodents. His
 views on the transmission of plague in South America may be contested. Less
 he says that if the domestic rat was the original reservoir among these people
 it has ceased to be important for the disease is to-day transmitted by human
 rather than rodent ectoparasites—that is to say by the human flea or even
 lice and from man to man. W F Harris

CHOLERA

BIRALD Y & KALL P M. World Distribution and Prevalence of Cholera in
 Recent Years. *Epidemiological & Social Statistics Rep. W.H.O. Internat.
 Commission* 1947 Dec. 1 No. 7 140-34 3 charts & 1 map. In
 parallel French & English.

This document on the recent cholera epidemic in Egypt is of great importance
 coming, as it does from the World Health Organization of the United Nations.
 In its explanation of the origin of the epidemic it follows standard and
 regulation lines. If that explanation is not wholly acceptable it simply means
 that ignorance still prevails on the subject of cholera, not so much perhaps on
 its epidemiology as on its endemology.

The epidemic was unexpected, and it is stated categorically that, 'Cholera still fully deserves its qualification of "Asiatic" because for the last thirty years it has been confined to that continent' There is abundant evidence that India is the most persistently affected part of Asia, but we learn that figures for British India are more reliable than elsewhere and that British India up to 1947 contained some three-fourths of the population of India Prominence of the cholera of British India may have something to do with the reliability of its statistics By British India is meant, for the most part, the Gangetic Valley and the city of Calcutta, although in the present case attention is directed rather to the Punjab Particular note is taken in this publication of those correlated factors in epidemic cholera —famine, war, pilgrimages and panic-stricken populations In India, the Japanese war menace, the Bengal famine and the large-scale movement of population as a result of partition are rightly noted

The earliest history of the present epidemic is very interesting, because "the first three cases were believed to be food poisoning," that is to say, presumably, something more severe than subclinical cholera or mild diarrhoea A very important factor in the subsequent development of the epidemic was that El Koreim, the focal point, was overcrowded with a non-resident population a stampede of this population spread the epidemic first over the lower Nile provinces and then over the upper Large cities with a chlorinated water supply and satisfactory sanitation escaped very lightly, as one may expect is the position of Europe to day compared with last century

Some note may be taken of the record that "the source of the epidemic is still obscure" and that "first-hand observers think they can trace the origin of the infection to Egyptian labourers infected by aeroplanes coming from India' The explanation offered seems to be that of the landing of a germ carrier from India There is positive evidence that cholera was absent during the Mecca pilgrimage in 1947 and that the epidemic broke out before the return of the pilgrims

A contention that vaccination of the whole population and the winter season, unfavourable to cholera prevalence, both played their part in the limitation of the outbreak might perhaps be met by opposing the remarkably similar graphs of cholera epidemic for 1902 and 1947 No vaccination can have been instituted in 1902 The longer duration of the epidemic in 1896 might reasonably be given as being due to the season of its occurrence, May to October We may note also the intention of the authorities to institute a vaccination campaign to cover the entire population in 1948 Practically no mention is made in this account of chemotherapy for cholera, among the highly commendable and energetic activities of the Egyptian authorities

GALLUT J & GRABAR P Recherches immunochimiques sur le vibron cholérique V Absence de pouvoir antigénique de la substance hypothermisante de la toxine cholérique [Absence of Antigenic Power in the Hypothermy-producing Component of Cholera Toxin] *Ann Inst Pasteur* 1947, Nov, v 73, No 11, 1139-42

Two different fractions are demonstrable in cholera toxin, one of large molecule ($d > 100 \mu\mu$), a conjugate protein of glucolipidic type, and another of small molecule ($d < 4 \mu\mu$) of unknown character, but causing hypothermy [this *Bulletin* 1943, v 40 910, 1944, v 41, 401 and 402, 1945 v 42, 807 1946, v 43, 129] The first component is identified as cholera O antigen and, as an antigen, furnishes a neutralizing antiserum This antiserum has no action on the second component The present research sets out to determine whether

the second component is antigenic and to investigate its specificity. The authors find that it is devoid of antigenic power.

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

REES C. W. & REARDON Lucy V. Problems on the Growth Requirements of the Parasitic Protozoa. *Liber Jubilaris J. Rothelm* (Soc. Belg. M. Trop. Brussels) 1947 Dec. 303-25. [80 refs.]

This paper is a review of literature dealing with the cultivation of *E. histolytica*, various Trichomonadidae, pathogenic trypanosomes and leishmanias and species of *Plasmodium* with particular reference to the constituents of the media employed. The various papers referred to have been reviewed in this Bulletin.

C. M. Wrenn

SPRINGARN C. L. & EDLGMAN M. H. The Prolongation of the Viability of Cultures of *E. histolytica* by the addition of Streptomycin. *J. Parasitology* 1947 Oct. v. 33 No. 5 416-18.

The authors have found that cultures of *Entamoeba histolytica* on Difco amoeba medium covered with horse-serum saline and having rice particles added progress satisfactorily when subculture is made every 48 hours. Act. amoebae can be found in these cultures up to the 8th day. After the addition of 1 (000) 3 (000) units of streptomycin to the serum saline, amoebae grew in rare instances, but after 24 to 48 hours the amoebae were fewer than in the controls, though they appeared to be normal in size and motility and in their power to ingest rice. The average survival time in streptomycin cultures was 33.7 days in contrast to 8.0 days in controls. Some cultures survived 40 or 50 days and one 70 days. In the streptomycin tubes bacterial growth was markedly inhibited.

WRIGHT A. W. & COOMBS A. E. R. Treatment of Amoebic Dysentery. *Lancet* 1948, Feb. 14, 743-6. 3 figs. 20 refs.

Not only was the incidence of amoebic infection in India Command down to that of the average pre-war rate, but response to treatment was poor.

The importance of early diagnosis became clear. On the day after admission sigmoidoscopy was done as a routine. A warm stage and warm saline were used and material from rectal or sigmoid swab was immediately examined under the microscope.

Emetine bisulphate was frequently given in tablets. In three patients it was ascertained by radiography that they were not being absorbed. These cases and a number of others similarly treated showed no grey discoloration of the stools, such as is seen after proper administration of E.H.I. Early in the investigation it became apparent that though fresh cases responded well to thorough course of treatment, the relapsing cases and those with a long history before treatment did not. A further important factor appeared to be a secondary bacterial infection. Isolation of a pathogenic organism or the finding of a bacillary exudate was taken as evidence of such an infection, which was proved in 41 per cent of cases. The incidence was not significantly greater in chronic than in fresh cases. On these premises, course of treatment was devised.

consisting of 2 mega units of penicillin and 65 gm succinyl sulphathiazole followed by E B I and quinoxyl enemata for 12 days and carbarsone for 10. In all, 92 patients were given penicillin. Sigmoidoscopy was carried out before and after this treatment and in every case where ulceration had been seen there was striking improvement.

On the completion of treatment, the patient was retained in hospital for ten days, during which 6 stools were examined and sigmoidoscopy was done. After a period of three weeks in a convalescent depot, he returned to hospital for a week. Three more stools were examined and sigmoidoscopy was repeated. If he was apparently cured, he was discharged and required to report by postcard in three months' time. The importance of sigmoidoscopy is emphasized, as lesions suggesting amoebiasis were present in 88 per cent of cases with negative *E. histolytica*.

In 21 per cent of cases, the organisms were present in the swab when the stool was negative.

Cure was effected in 97.5 per cent of primary cases with symptoms lasting two months or less, 96.1 per cent of all primary cases were cured, 85 per cent of those with one previous attack, and only 58.4 per cent of those with more than one attack.

P. Manson-Bahr

MANSON-BAHR, P & MUGGLETON, W. J. The Response of Intestinal Amoebiasis to Diodoquin Treatment. *J Trop Med & Hyg* 1948, Feb v 51, No 2, 23-7 [10 refs]

The authors treated 71 patients suffering from intestinal *Entamoeba histolytica* infections with Diodoquin (Searle). The dosage was two tablets (6.4 grains) four times daily after food for fifteen days. The patients could be divided into four groups as follows—

Series I—Six with acute amoebic dysentery. The drug proved valueless in these.

Series II—Twelve with a history of amoebic dysentery in the preceding five years but quiescent at the time of treatment. One had an acute clinical relapse within three weeks, eleven were free from cysts three to sixteen weeks after treatment.

Series III—Twenty-three with a history of previous diarrhoea. One continued to pass cysts throughout and after treatment twenty-two were free from cysts three to 104 weeks after treatment.

Series IV—Thirty apparently healthy carriers with no history of diarrhoea. All were free from cysts three to 120 weeks after treatment. [Six was the maximum number of stools examined in any one case of the four series.]

There was no evidence of genuine toxic action of the drug in the 71 cases. Sigmoidoscopy or proctoscopy, where these were done, showed typical amoebic ulceration in the Series I cases, a pigskin type of pitting in the Series II and III cases and a normal mucosa in the Series IV cases.

The nature of the infection in the carrier, or symptomless cyst-passer state, is discussed. The authors incline to the view that *E. histolytica* lives in the lumen of the bowel as a coprozoic organism in some cases. This type of infection is eradicated by diodoquin, which is an efficient drug for this purpose as it is dispersed in the intestine and is not absorbed to any material extent. Cysts of non-pathogenic amoebae, and of *Giardia intestinalis* when these were present, disappeared after diodoquin treatment but the latter reappeared within two months.

J. R. D. Adams

Coxam N. J., Jr. Chloroquine in Amoebiasis. *Amer J Trop Med.* 1948 Jan. v 28 No 1 107-10.

In view of the occasional toxicity of emetine, it is desirable to have a safe and non-toxic substitute for it in the treatment of amoebic involvement of the liver. Some members of the 4-aminoquinoline series, which have a high antimalarial activity can be given in a non-toxic dosage which is associated with localization in high concentration in tissues especially the liver.

The author studied the anti amoebic activity of one of these compounds, chloroquine (see this *Bulletin* 1948, v 45 37). He quotes the work of BERLINER *et al.* (in the press) indicating that this drug is localized in the liver of the rat in concentrations 400 to 600 times those in the plasma.

A table shows that *in vitro* chloroquine had an amoebicidal activity greater than that of Anayodin and Carbarsone but less than that of emetine. In human amoebiasis, chloroquine was given firstly as a priming dose to saturate the tissues and rapidly obtain the equilibrium plasma concentration and secondly as sustaining doses for 2 or 3 weeks. The doses used were far in excess of those required for antimalarial activity and were about one-half of the believed minimal toxic dose, as estimated by Berliner *et al.* The priming doses consisted of 0.3 gm. of the base twice daily for 2 days and the sustaining doses were 0.3 gm. daily for 12 or 18 days more—all doses were given orally.

In these experiments plasma concentrations of the drug were not determined but from the work quoted above it is indicated that they would amount to about 150 microgrammes per litre. No toxic symptoms were observed, but two patients with amoebic hepatitis had mild and transient gastric symptoms. Altogether 28 patients with intestinal amoebiasis and 6 with amoebic hepatitis were treated with Chloroquine. Thirteen of the former continued to show parasites in the stools after one course of treatment—the other 15 had persistently negative stools for 2 to 8 months. The author emphasizes that as the follow-up period lengthens the figures can only change unfavourably.

In the 6 cases of amoebic hepatitis, symptoms and signs disappeared sharply within a few days of the beginning of treatment—they have not recurred within 2 to 1 months.

The drug had no effect on non-pathogenic intestinal protozoa or on a number of species of helminths.

As chloroquine is almost entirely absorbed from the gastro-intestinal tract, its effect on amoebae in the colon must be due to plasma or tissue concentration.

The author states that this report is wholly preliminary and its primary purpose is to call attention to the anti-amoebic activity of this non-toxic drug and to encourage others to test it especially in amoebic hepatitis.

H. J. O'D. Burke-Gaffney

FELTON J. D. & JOYNER L. P. Natural Amoebic Infections in Laboratory Rodents. *Nature* 1948 Jan. 10 68-8 6 figs. 110 refs.

In the course of chemotherapeutic work on *E. histolytica* the following animals were examined for naturally occurring amoebic infections—white rat, cotton rat (*Sigmodon hispidus*), hamster (*Cricetus auratus*), Orkney vole (*Microtus oeconomus*). In all of these an amoeba resembling *Entamoeba coli* was discovered in 50-70 per cent of animals examined. The amoebae and their binuclear cysts are illustrated in microphotographs. Attempts at cultivation of the amoebae failed.

C. M. Henry

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

GAUD, M & MORGAN, M T *Epidemiological Study of Relapsing Fever in North Africa (1943-1945)* *Bull World Health Organization* (United Nations) 1947/48, v 1, No 1, 69-92, 1 map & 2 charts

An U.N.R.R.A. Mission consisting of Dr Gaud and Dr Morgan proceeded to French North Africa in November 1945 in order to study the epidemic of louse-borne relapsing fever which, after 25 years' quiescence, had spread rapidly through Tunisia, Algeria and Morocco. The last epidemics were in North Africa between 1912 and 1915 and in French West Africa between 1922 and 1925. During the intervening period, only small foci of the tick-borne disease existed.

This study is divided into three parts: epidemiological, clinical and therapeutic. It was shown that the origin of the epidemic was in the Fezzan region of southern Tripolitania. This was also thought to be the reservoir of the virus in the 1912 epidemic by NICOLLE (whom the authors frequently quote and whose work permeates the whole story of relapsing fever). The disease apparently began in the nomad tribe of Megarha in the last quarter of 1942. Caravans spread the disease throughout the Fezzan and half the population became infected between November 1942 and May 1944 when the infection died out. The neighbouring countries, however, passed on the infection, which eventually reached Morocco in the west. In Tunisia, approximately 400,000 cases occurred (20 per cent of the population); in Algeria, 432,000 (5 per cent of the population); in Morocco, perhaps 180,000 cases.

The epidemic was associated with a grave economic crisis, which has long been recognized as an essential precursor of louse-borne epidemics. Contrary to the classical notion that cases should be most numerous in the winter, on this occasion, there was no seasonal trend and the epidemics developed rapidly, irrespective of the season of their inception.

No actual evidence is cited that the louse was the vector of the disease in North Africa, though it was assumed to be so. The role of the bed bug was investigated and work at the Casablanca Pasteur Institute has shown that these insects can become infected by biting an infected person and that they are still infective after the first moult, as can be proved if they are crushed and injected.

The use of DDT has revolutionized the methods of control and the systematic use of this insecticide has proved completely efficacious. The inhabitants welcome this method which they recognize as valuable and harmless. Unfortunately, supplies of this substance do not appear to have been adequate and there is no mention of its widespread use. In fact the history of the epidemic itself shows the lack of effective control.

The clinical features were varied and every organic system was affected. Headache was always violent, and accompanied by bilious vomiting and pain in the joints. There was usually only one relapse, which ensued after a week's apyrexia. The most frequent complications were hepato-nephritis and peripheral haemorrhages. Neurological forms occurred, especially pseudotumoural conditions and various psychoses. Ophthalmic complications were numerous. Some of these were associated with the arsenic therapy. Premature termination of pregnancy was virtually inevitable and this is ascribed to the death of the ovum after an enormous drop in the proteins in the maternal blood which leads to dehydration and cachexia.

Mortality figures cannot be assessed accurately, but apparently varied in hospital cases from 3.6 per cent in the well-to-do to 87 per cent in the poverty-stricken. In the untreated, the figure varied between 5 and 10 per cent.

Different spirochaetocidal drugs were employed—antimony bismuth and mercury salts were relatively inefficacious. Pentavalent arsenic was successful in curing the infection, but was sometimes followed by ocular disasters. The best drugs were the less toxic trivalent compounds (Neocarsphenamine, Maptarsen). The standard course of the former was 0.3 gm. the first day, 0.45 gm. the second and 0.6 gm. the fourth. An interesting new method was employed on 32 cases, namely treatment with convalescent serum (20 cc. intravenously) 80 per cent. of the patients so treated were cured in 12 hours.

The authors conclude by stating that the immense region along the South Coast of the Mediterranean is the real sanitary frontier of Europe, a frontier easily crossed because the Mediterranean is a sea which unites rather than divides—beyond this frontier all the major epidemic diseases are rampant.

P. C. C. Gurnham

GAUD M. KHALIL Bey M. & VALCEL, M. The Evolution of the Epidemic of Relapsing Fever 1942-1946. *Bull. World Health Organization* (United Nations) 1947/48, v. 1 No. 1 83-101

This paper forms a corollary to the one abstracted above (GAUD & M. KHALIL) and describes the extension of the epidemic throughout North Africa and the Middle East. The chronology of the disease in the larger field appeared to be as follows—

| | |
|-----------------------|-------------------------|
| Last quarter of 1942 | Fezzan, S. Tripolitania |
| October 1943 | Tunisia |
| November 1944 | Algeria |
| Early 1945 | Morocco |
| November 1945 | Tangier |
| 1945 | Egypt |
| 1945 | Kenya |
| February to June 1945 | Iran |

The epidemic traversed the whole of North-West Africa like a storm. Eastwards the disease was first recognized at Asut in October 1944 but this threat to Egypt did not materialize until the following year, during which and in the first half of 1945 over 100,000 cases were reported, the peak notifications being in April 1946. Throughout 1945 and 1946 small numbers of cases occurred in the Middle East including Transjordan, Palestine Syria, Iraq and Aden. The disease attained epidemic proportions in Kenya and Iran.

The threat to French West Africa was partly averted by the instatement of strict sanitary measures at Dakar on the arrival of convicts, but there is nothing to prevent the importation of the disease by land and the danger of this country remains great.

Relapsing fever in epidemic form in Europe was confined to Rumania, where over 5,000 cases occurred in the first six months of 1946. It is unknown whether there is an aetiological connexion between this flow and the outbreak in North Africa.

The epidemic started as a few cases in a semi-desert region, progressively invaded the whole of North Africa from the Atlantic to the Red Sea, and is now threatening Central Africa and Europe.

P. C. C. Gurnham

SALLER, L. La fièvre récurrente à Fés (1945-1946). *Relapsing Fever in Fes*. *Cahiers M. d'Union Française* Algiers 1947 June No. 11 431-7

The author states that the infection seems to have been brought into Fes by agricultural workers from the Oujda area in May 1945. The number of

cases reached a maximum in September, since when it has persisted at a somewhat lower level. Lice, and "probably" bugs, are considered to be the carriers [There is no evidence in support of this statement] The author observed and treated more than 1,000 cases during eight months ending January, 1946

The incubation is said to be very short, only 2 or 3 days, and the author states that he was bitten by a louse on Wednesday at 8 p.m., and developed a febrile attack on Saturday at 2 p.m. A few observations are given on the clinical symptoms of the patients. The treatment adopted was acetylarsan, during the first 48 hours, and Mapharsen or Fontarsan when the infection was at its height

E Hindle

BODMAN, R. I. & STEWART, I. S. Louse-borne Relapsing Fever in Persia. *Brit Med J* 1948, Feb 14, 291-3, 2 charts [14 refs]

Between November, 1945, and June, 1946, an epidemic of louse-borne relapsing fever occurred in Abadan, 1,087 cases being admitted to the isolation hospital. The authors have found no report in the literature of louse-borne relapsing fever in Persia, but the present epidemic was undoubtedly part of the widespread epidemics in the Mediterranean and North Africa during 1943-45. The epidemic closely followed the cold weather, and quickly declined as the general temperature began to rise. Charts comparing this outbreak with a typhus epidemic in Abadan in 1943 show a striking similarity in the critical temperatures for the termination of the epidemics.

The diagnosis of louse-borne infection was based on the following points: (1) No tick focus has been found in Abadan and it is believed that no human ticks occur there. (2) Lice were found to have infested 88 per cent of the patients admitted to the isolation hospital. (3) *Trep. recurrentis* was found in lice taken from the patients. (4) The epidemiological features were characteristic. (5) Mass disinfection with DDT powder caused a drop in the weekly admissions.

Special clinical examinations were made of the last 214 cases admitted. Most of these patients were young adult males of the labouring and unemployed classes. The symptomatology is described. A point of interest was the frequency with which patients could fix the time of onset which was ushered in with a splitting frontal headache. The period of apyrexia lasted about 9 days, although the most constant time-relationship was from onset to relapse, which averaged 14 days. Rashes were rarely seen, in those few patients having a petechial rash on the trunk, the Weil-Felix reaction showed only a slight *Proteus* OXK agglutination (e.g., 1/25+, 1/50±). Jaundice was not uncommon; in 9 cases it was marked, and this was a bad prognostic sign—two of such patients died. The spleen showed all degrees of enlargement. The percentage incidence of symptoms and of signs is shown in tabular form and the authors note that the central nervous system is predominantly affected. 90 per cent of their patients complained of headache and 77 per cent of backache in the thoracic and upper lumbar regions. Two patients had mental derangement and there was one case of transverse myelitis. These last three were however the only complications seen in the central nervous system. Respiratory complications were the commonest amounting to 60 per cent; they varied from 'cough' to bronchopneumonia. The overall death rate amounted to 1.11 per cent.

The 214 cases specially studied were treated in two groups. Group I (97 patients) were given 0.45 gm. NAB intravenously on admission. 11 patients relapsed once. In group II (117 cases) the dose was not given until the case

relapsed, which occurred in 73 cases. This saved the drug, which was short at the time and also demonstrated its effectiveness in group I.

Few reactions followed the injection of VAB—no definite time interval was noticed between the injection and the crisis.

Of the nine patients with marked jaundice three were not given VAB on admission owing to the liver damage already present. Two of these three died. The remaining six received VAB on admission and none of them died.

BALTAZARD M. BAHMANYAR, M. & MOFII C. *Fébriles récurrentes transmises à la fois par ornithodores et par poux.* [Relapsing Fevers transmitted both by *Ornithodoros* and Lice.] *Ann. Inst. Pasteur* 1947 Nov v 73 No 11 1066-71

The authors have shown the resemblance between *Spirochaeta citri* and certain strains of spirochaetes occurring in rodents and *Ornithodoros* (see this Bulletin 1947 v 44 906).

In a first series of experiments, various batches of *Ornithodoros erraticus*, *O. lahorensis*, *O. turicata* and *O. parkeri* were fed on newly born rabbits heavily infected with *S. citri* and subsequently tested for infectivity with uniformly negative results.

In a second series human lice were fed on newly born rabbits infected respectively with a strain of *S. maritimi* from *O. erraticus* obtained in Persia, and *S. turicatae* and *S. hermsi* both North American strains isolated from *O. turicata* and *O. hermsi* respectively. The lice were fed once on a heavily infected rabbit and subsequently maintained on a human subject. After intervals ranging from 9 to 12 days the lice were ground up and inoculated into newly born rabbits. In every case these became infected, showing that these naturally occurring rodent strains although normally transmitted only by ticks belonging to the genus *Ornithodor* are also capable of survival in the human body louse. E. H. Adie

WOLSTENHOLME B. & GEAR, J. H. S. *A Complement Fixation Test for the Diagnosis of Relapsing Fever.* *Trans. Roy. Soc. Trop. Med. & Hyg.* 1948 Jan v 41 No 4 313-17

It is notoriously difficult to find *T. p. dubium* in many chronic infections of relapsing fever during the afebrile intervals. The authors have therefore devised a complement fixation test as an additional diagnostic aid.

The antigen is prepared by establishing *T. p. dubium* in egg-culture. This is achieved by inoculating eight fertile eggs on the 7th day of incubation, through the blunt air sac end, with 0.4 cc. of heart blood from an experimentally infected mouse. After a week incubation at 37°C. the eggs are opened, and the blood vessels of the chorio-allantoic membrane are torn and allowed to bleed into the allantoic fluid. This mixture serves as an inoculum (0.1 cc.) for further batches of eggs, the trays from which, in the authors' case have been subcultured for ten weekly passages with somewhat variable growth of spirochaetes.

A sample of the blood-allantoic fluid mixture is examined by dark ground and stained smears, and it is only used if the degree of infection is profuse (e.g. 50 to 100 spirochaetes per field). The harvested fluid is centrifuged at 1,000 r.p.m. for 5 minutes, and the supernatant then centrifuged for 3 hours at 7,000 r.p.m. The resulting white sediment represent the spirochaetes, and the supernatant allantoic fluid is now replaced with 0.3 per cent sterile phenol saline. When this is shaken an even suspension is obtained and this constitutes antigen.

its anti-complementary properties were found to be low and it could be used undiluted [For detailed steps in the egg-culture and preparation of the antigen, the original paper should be consulted.]

For the test, the sera were inactivated at 56°C for 30 minutes and serial dilutions were made from 1/12.5 to 1/100 and thereafter to 1/3,200

Tubes corresponding to each dilution were set up and to each was added 0.1 cc of the appropriate serum dilution and 0.1 cc each of 3 M H D gunea-pig complement and of undiluted antigen. One extra tube was used as an anti-complementary control and contained 0.1 cc of normal saline instead of antigen. The tubes were placed in a 37°C water bath for one hour, when fixation took place. To each tube, 0.1 cc of 3 per cent washed sheep cells, sensitized with 6 M H D of amboceptor, was added and the tubes were incubated at 37°C for a further 30 minutes, after which the results were read.

A table shows the results of the test in 6 confirmed cases of relapsing fever. All gave a positive result in a titre of 1/25 and five of the six were + or ± at 1/100.

Twenty-four sera sent for routine blood grouping were negative, of thirty sera giving a strongly positive Wassermann reaction, one was anti-complementary in the present test, 4 gave a ± result at 1/12.5 and the remaining 25 were negative. Seven sera from patients suffering from typhus, rheumatic fever, malaria, virus pneumonia and tuberculosis were negative, with the exception of one serum from a case of typhus fever which was positive at 1/12.5. All these tests were adequately controlled.

The authors conclude tentatively that fixation of complement in a titre of 1/25 and over should be taken as "diagnostic" of relapsing fever.

The time of development of the specific antibodies and the period of their persistence after apparent cure will be investigated, but in one case it was shown that these antibodies were present in low, though provisionally diagnostic, titre at the end of the first bout of fever. A point of interest is that in four of the six known cases of relapsing fever, blood films were negative for spirochaetes at the time the blood was taken for the complement fixation test.

The authors suggest that this complement fixation test promises to be of value in cases where finding the spirochaete in the blood is unlikely, in surveys of the incidence of relapsing fever, and possibly as a test of cure, though this aspect has not yet been studied.

DEANE, Maria P. Verificação da infecção natural de ratos por *Leptospira icterohaemorrhagiae* na cidade de Belém, Pará [Natural Infection of Rats with *Leptospira icterohaemorrhagiae* in the City of Belém, Pará] *Rev. Serviço Especial de Saúde Pública* Rio de Janeiro 1947, July, v 1, No 2, 261-71. English summary.

In Belém, northern Brazil, the author found a natural infection with *Leptospira icterohaemorrhagiae* in 4 of 15 *Rattus norvegicus*, 4 of 19 *R. rattus* and 3 of 22 *R. alexandrinus*.

Infection was detected by dark-ground examination either of urine or of kidney suspension or both and by animal inoculation. Eight strains were highly virulent for white mice. Of 104 white mice inoculated with infected material, 28 died of causes other than leptospirosis, the remainder were jaundiced and usually showed pulmonary haemorrhages at postmortem. A few mice without jaundice recovered and later showed leptospirae in the urine, two of them were still passing these organisms in the urine after 3 months' observation. Young white mice (3-4 weeks) proved very susceptible as laboratory animals.

Strains from wild rats were grown on Verroot's medium and .5 per cent. rabbit serum in the medium instead of 0.5 per cent. provided the best results.

A strain which proved infective to chick embryo appeared to take an increased virulence since after passage, it killed 3 mice in 4 to 5 days, although previously it had killed mice in 10 to 14 days.

No human cases of Weil's disease have been recognized in the Amazon region so far but in view of the comparatively high infection rate in rats in Belém and the potential opportunities for human infection it is important that medical practitioners should have the possibility constantly in mind.

Section des Sciences Naturelles et Médicales. Mémoires*. (Collection in-8°) 1940 v. 10 No. 2, 60 pp. 1 map. (Bibliography)

This report gives a valuable summary of the measures for long in use in the Belgian Congo for the control of leprosy, and is based on reports by many medical workers, which should be read by leprologists especially those engaged in similar work in backward tropical areas.

Agricultural colonies for leprosy patients have been instituted in this territory since 1927 mainly under the care of medical missionaries. Since 1937 a Commission has collected information on the endemicity of the disease which was condensed in a report by Dr. VAN HOOB, the chief medical officer on which the present publication is based. The geographical distribution of leprosy is first dealt with: at the end of 1938 the known cases were estimated 1617, or a mean of about 0.55 per cent. of the population. This is considered to be a maximum figure as other skin diseases are sometimes erroneously diagnosed as leprosy. Tables at the end of the report show 18438 as segregated including many patients with neural disease. It is not possible to say if the incidence is increasing or not. The north shows higher rates than the south. Another table shows 64,534 under treatment. The number of children infected is low except in highly infected areas, and females suffer nearly as much as males. The proportion of lepromatous cases is only 10 to 15 per cent. of the whole; the disease is therefore of a mild type in this region though advanced or disfigured cases are seen. It is not held that the nerve type is completely nonexistent though the main sources of infection are the lepromatous cases.

The report goes on to deal with local variations in incidence and records a detailed survey of three highly infected villages with up to 10 per cent. of their occupants infected. The interesting suggestion is made that it would be simpler

in their case to remove the healthy than to isolate all the infected elsewhere. The great difficulties in dealing with a highly infected area of very poor and backward people living in a high degree of general and sexual promiscuity is well brought out. The commonest exposure to infection is domestic. Some differences of opinion are quoted regarding the effectiveness of chaulmoogra preparations and some doctors advocate their intravenous use.

Lastly, prophylactic measures are dealt with and preference is given to agricultural colonies containing about 300 persons frequently visited by a European doctor. At present these colonies contain a large proportion of neural cases, but the question of isolating only the more infective lepromatous patients is under consideration. A Government circular of 1937 on the campaign against leprosy is reprinted in this interesting publication.

YBARRA PÉREZ, R & GONZÁLEZ PRENDES, M A. *La lepra y el estado civil de los enfermos de lepra en Cuba* [The Civil State of Leprosy Patients in Cuba]. *Rev Sifilografía, Leptología y Dermatología* Marianao, Cuba 1947, Apr, v 4, No 2, 72-6

The author gives figures which indicate that the percentage of married persons suffering from leprosy among the sick population in Cuba is 15.67 per cent higher than that of the married persons in the whole of the healthy population of that country, but the percentage of those in hospital is less than that of the ambulatory cases, owing to a number of social conditions.

On the other hand, the percentage of unmarried persons with leprosy among the sick population is 16.58 per cent less than that of the unmarried in the whole population, and the percentage of ambulatory cases is less than that of the unmarried hospital patients.

The social causes and significance of these findings are discussed.

H J O'D Burke-Gaffney

FLOCH, H. *On the Epidemiology of Leprosy in French Guiana*. *Internat J Leprosy* Cleveland, Ohio 1947, Apr-June, v 15, No 2, 183-8

This is an instructive account of a careful inquiry on modern lines. In the course of 21 years 1,447 cases of leprosy were registered, of whom 1,131 remain, or 5.1 per cent of the population, a lower figure than earlier estimates. Altogether, 253 occurred among the penal population 157 of whom were Europeans. Early cases have been sought for, and the unregistered cases are estimated not to exceed 300, bringing the total incidence to 6.5 per cent. There were 710 males and 478 females. Children up to 15 years of age formed 43.8 per cent, and persons over 25 years formed only 37.7 per cent of the whole. Examinations of school children showed that 49 per cent of new cases occurred in children up to 15 years of age. Contagion among school children is real and the results of segregating all those discovered resulted in a progressive diminution of new cases in the schools, from 26 in 1939 to only 8 in 1945. The disease is not hereditary and familial infection is a proven fact. A servant had apparently infected five infants under her care. A table indicates transmission to collateral more often than to direct descendants. In children the maculo-anaesthetic form is most frequent, and it is considered to be the least dangerous. On the other hand, Europeans are usually only infected after long residence and with a longer incubation period than in the case of indigenous

children who appear to be more susceptible. The proportion of progressive and serious types is greater in Europeans, who appear to have less resisting power than the indigenous people—this indicates the presence of a relative immunity among the Creole population, who have long been exposed to infection. Mitsuda reactions were positive in 90 per cent. of tuberculoid, 51 per cent. of neural, 1 in 12 of mixed cases, and were negative in all lepromatous ones. In healthy children under 10 years old, no positive reactions were met. An attempt to immunize children by inducing positive reactions is suggested.

RIZZ, J. B. Frequency of the Clinical Types of Leprosy according to the Natural Regions of Brazil. *Internat. J. Leprosy* Cleveland, Ohio. 1947 July Sept. v 15 No. 3 246-57

Tables are given of the incidence per mille and the percentages of the different types of leprosy in relation to geographical and climatic conditions. The very hot humid Amazon river basin shows the highest rates of 1 to 3.8 per mille but with fewer severe lepromatous cases. On the contrary the dry north-east region has the lowest rates of 0.9 to 0.1 per mille, but with a larger proportion of lepromatous cases. The eastern, southern and west-central regions, with cooler climatic conditions, present intermediate data. The author agrees with Rogers that hot humid climates favour the spread of leprosy and he thinks that they act by adversely affecting the body metabolism rather than by an indirect effect in favouring the transmission of the disease [Rogers suggested that the innumerable insect bites of hot damp climates favour the entry of lepra bacilli from contact cases through the puncture or abrasion lesions of the skin.] The author also suggests that humidity favours a less severe evolution of the disease and that a cold climate favours more acute development.

MENDY P & MANGON G. Leprosy in the State of Rio Grande do Sul. *Internat. J. Leprosy* Cleveland, Ohio. 1947 July Sept. v 15 No. 3, 254-63.

DUBOIS, A. Classification de la lèpre [Classification of Leprosy] *Ann. Tropica* Basle 1947 v 4 No. 4 289-97

The author criticizes the classifications of South American workers and that of TISSOT as leaving many difficulties, especially for the clinician, in the neural cases. He suggests classification based on the amount of bacillary invasion of the tissues, as determined by simple routine examinations, rather than on less easily ascertained histological grounds, and suggests the following classification, in which the old symbols are shown after each form in brackets.

A.—Bacilli rare or absent. Subdivisions A M flat macules (Na) A A anaesthetic-acrotic (Na) A M A maculoanaesthetic (Na-Na) A T elevated macules, tuberculoid major (NT) A-t elevated macules tuberculoid minor (Nt) A T A (or t A) elevated macules with lesions of nerves (NT (t)-Na).

B.—Bacilli numerous (++ or + -) B.M. Macular (Lm) B.L. Lepromatous, nodular (L1,2,3) B.I. do. localized infiltration. (L1-3) B.D. do. diffuse infiltration (Ld) B.G. do. generalized B.A. anaesthetic-acrotic (LN) A anaesthetic-acrotic (secondary)

PORTUGAL, H **Contribution to the Study of the Classification of Leprosy Aspect of Lesions, Antigene Response, and Presence of Micro-Organisms in Histologic Structure** *Internat J Leprosy* Cleveland, Ohio 1947, Apr-June, v 15, No 2, 162-8

In this paper, the practical application of the South American classification is considered in the light of histological examinations in 70 cases, in the majority of which an immediate diagnosis of type was possible. In others, time was required to watch the evolution. Among 13 lepromatous cases, mostly fairly early ones, all were positive bacteriologically and gave negative Mitsuda reactions. Moreover, the lipid staining test was positive except in very early cases. The tuberculoid group included reacting and quiescent cases. One reacting case developed into the lepromatous type during eighteen months; a second remained tuberculoid and in a third the evolution remained doubtful. Among 32 quiescent cases, the majority being of one to six months' duration, all were uniformly tuberculoid and negative bacteriologically to routine examination and all but two were positive to the Mitsuda test. The "uncharacteristic" type numbered 18; they mostly showed achromic or hypochromic spots or merely anaesthetic areas. Only two showed bacteria and half were Mitsuda positive and half negative. In all, only small lymphocytic infiltration was found around the small vessels. In two cases, tuberculoid structure developed later. Re-examinations were not done in a number of these cases, so their evolution is uncertain and no one can foretell their outcome. They may remain "uncharacteristic" or may evolve into tuberculoid or lepromatous cases.

RODRIGUEZ, J N **Observations on the Classification of Leprosy** *Internat J Leprosy* Cleveland, Ohio 1947, July-Sept, v 15, No 3, 274-302 [52 refs]

This is a full discussion of this difficult subject which should be read by all leprologists. The author first traces the evolution of classification from the old Norwegian one of "nodular" and "anaesthetic" up to the recognition of a third or "tuberculoid" type by the Cairo Congress in 1938, based on histology largely due to the work of WADE. This was soon recognized to be still inadequate, especially by South American pathologists, which led to the adoption, by the Second Pan-American Conference at Rio de Janeiro in 1947, of the following types:

Uncharacteristic (I) or Unidentified, Macular, Neural or Neuro-Macular Lepromatous (L), Macular, Infiltrative, Nodular, Neural and Generalized Tuberculoid (T), Macular, Papular, Neural and Reactive.

It differs from an earlier South American classification in raising the "uncharacteristic" form to the status of a fundamental type. Its scientific basis is histological, for the uncharacteristic type is characterized by the presence of only simple round-cell infiltration, as opposed to the tuberculoid granuloma and foamy-cell infiltration respectively of the other types.

The present author proposes to add a fourth type, characterized by only interstitial proliferation as found in the maculo-anaesthetic (neuro-lepid) and he calls the second type with round-cell infiltration simple macular (lepid). He further discusses the question of the evolution of tuberculoid into lepromatous disease and accepts the evidence of South American workers who followed the change of typical Mitsuda- or lepromin-positive tuberculoid cases into negative reacting lepromatous cases as proof of such a change although it usually takes a long time to be brought about. He also discusses the difficulty in classifying the common "neural" cases which require further biopsy studies. He suggests that the lepromatous form is the characteristic fully

developed leprosy in non-resisting patients and the other three types are either benign atypical cases or evolutionary forms of the earliest stage of the disease. The histological classification cannot be adopted by the great majority of those working in the field at the control and treatment of the disease for want of time and opportunities for making biopsies. He therefore proposes the following subdivisions of the four fundamental types —

1 *Interstitial*. MA_1 (Mitsuda positive or negative) MA_2 (moderate atrophies, Mitsuda positive) and MA_3 (marked atrophies, paralysis, trophic ulcers, Mitsuda strongly positive)

2 *Perivascular Round-Cell* (Uncharacteristic stage.) Mitsuda plus or minus RCpt pre-tuberculous (lepid) RCpl, pre-lepromatous RCr residual

3 *Tuberculous Stage* (T) (Mitsuda positive) T simple (typical or minor) Tm, macular Tmp, maculo-papular or papular Tmn or Tmpa, with nerve involvement TR, reacting tuberculous (major) TRn, with nerve involvement Tr residual Tlaz, lacerate leprosy (hyperergic)

4 *Lepromatous* (foamy cell) type (Mitsuda negative) C_1 C_2 C_3 with or without N_1 or N_2

For further detailed description of the above forms, the original paper must be consulted. A good bibliography is appended. L. Rogers

DE SOUZA LIMA, M. BARBA RUBIO J., DE SOUZA LIMA, L. & RATH DE SOUZA, P. Pathogenic Bases of the South American Classification of Leprosy. *Internat. J. Leprosy* Cleveland, Ohio. 1947 Apr June v 15 No. 1, 169-74

This paper deals with the pathogenesis of leprosy in relation to immunology and the histopathological structure of the lesions, with a view to explaining the mutations from one type to another which occasionally occur. *M. leprae* on entering the human host can survive for long in the interstitial connective tissue without multiplying actively until it succeeds in penetrating into living cells. The bacilli are then phagocytosed by macrophages and histiocytes, which may react by destroying the bacilli by lysis in resistant tuberculous forms or the bacilli actively multiply in the cells to form the typical foamy cells seen in lepromatous cases with little resistance to the invasion. When the body cells remain indifferent and non-reactive the "uncharacteristic" type results for a time. The two types of reaction may occasionally occur in the same lesions as a transitional form of an unstable nature the ultimate development of which is doubtful. In such the action of drugs or other favorable influence may produce a structural change from lepromatous to the tuberculous type. The South American classification is based on clinical, immunological and histological grounds. L. Rogers

AULAY R. D. The Mitsuda Test in Non-Leprous Persons in a Non-Endemic Country. *Internat. J. Leprosy* Cleveland, Ohio. 1947 July Sept. v 15 No. 3, 234-8.

1 Among 73 American adults of both sexes but predominantly Negroes 74 per cent reacted positively to full strength lepromin, but only 33 per cent to a 1:10 dilution of the same lepromin

2 Among males, 63 per cent reacted positively and among females 83 per cent

3 Concentration of bacilli in the antigen is important and should be standardized if results are to be compared

4 The authors believe that the mechanism of the Mitsuda phenomenon is due to a basic constitutional activity of the tissues. This natural tissue response may be accelerated either by *M. leprae* or *M. tuberculosis*

PORRITT, R J & OLSEN, R E Two Simultaneous Cases of Leprosy developing in Tattoos *Amer J Path* 1947, Sept, v 23, No 5, 805-17, 8 figs on 3 pls [10 refs.]

This is an important contribution to the disputed question as to the inoculability of leprosy. The authors quote the opinion of JEANSELME that there is no adequate proof of the transmission of leprosy by inoculation, and also cites cases reported by ROGERS and MUIR to the contrary effect. They now record the cases of two men of the U S A Marine Corps, who were tattooed successively by the same man on the same day in June 1943, at a time when both the soldiers and the tattooer were drunk. Two and a half years later, in 1946, both men developed discoloured anaesthetic patches around the new tattoo marks, but an earlier tattoo mark in one was not involved. Portions of the lesions were removed for examination in both men without any discomfort in spite of the fact that no anaesthetic was used. Guinea-pigs were inoculated, with negative results as regards tuberculosis. Sections of the tissues of both showed typical tuberculoid changes, scattered acid-fast bacilli were readily found in one and less frequently in the other. The second patient developed similar patches on his other arm subsequently to those at the site of the tattoo mark. Sections of both were sent to the Carville Leprosarium, the authorities of which came to an unequivocal diagnosis of "typical tuberculoid leprosy". Both the naked-eye and the microscopical characters of the lesions are illustrated by plates.

The authors conclude that "These two cases provide strong evidence for the spread of leprosy by inoculation"

SCHUJMAN, S Therapeutic Value of Chaulmoogra in the Treatment of Leprosy *Internat J Leprosy* Cleveland, Ohio 1947, Apr-June, v 15, No 2, 135-45, 6 figs on 2 pls

The author stresses the necessity of early treatment of lepromatous patients by large doses of chaulmoogra oil regularly continued until the patients have remained free from symptoms for some time. He writes from seventeen years' experience and deals only with lepromatous cases, because other forms may recover spontaneously. He thinks reported failures are due to deficient doses and duration of the treatment. He finds that untreated lepromatous cases always become worse and those treated irregularly show an unfavourable evolution, but previously untreated cases nearly always improve, often rapidly, although renewed treatment after an interval is less certain and slower. Cases not benefited by small doses are benefited by larger ones and may become bacteriologically negative. The proper method is to inject the maximum amount which can be tolerated in the minimum time. All hospital patients who became clinically and bacteriologically negative had received a total dosage of 1,500 cc of ethyl esters, preferably with 4 per cent creosote, but of those showing only slight improvement, only 27 per cent had received the full dosage. The injections are made intramuscularly and intradermally. With the full dosage, 40 per cent of all treated lepromatous cases have been rendered clinically and bacteriologically negative, and 40 per cent have become definitely, and not only slightly, improved with the injection of a total amount of 30 cc weekly. The author is of the opinion that over 80 per cent of failures in lepromatous cases are due to deficient dosage and irregular treatment. The few failures are nearly all very advanced cases. Illustrative photographs of patients before and after treatment confirm the author's claims.

WHARTON L. H. Preliminary Report on a New Sulphonamide "Sulphetrons" *Internat. J. Leprosy* Cleveland, Ohio. 1947 July Sept., v 15, No. 3 231 S.

Sulphetrons in 3.0 Gm. daily dose giving 1 tablet (0.5 Gm.) every four hours has proved to be safe. We have seen only very mild toxic effects from the drug nausea, which was quickly relieved by administering sodium bicarbonate, 30 gr three times a day orally. There has been marked improvement in clinical symptoms, with flattening out of nodules. Bacteriological smears from nose and skin have shown marked improvement from month to month and one patient with positive nose and skin smears became bacteriologically negative in the fifth month.

It should be noted that this trial was made on early L_1 cases that were free from any complications of the disease. Clinical trials continue and will be extended to include patients with more advanced lesions, and with complications.

FAGET G. H. & ERICKSON P. T. Use of Streptomycin in the Treatment of Leprosy. A Preliminary Report. *Internat. J. Leprosy* Cleveland, Ohio. 1947 Apr-June, v 15 No. 2, 146-53.

The antibacterial action of streptomycin against the tubercle bacillus led to this trial. In 1945 the receipt of 50 million units allowed of only one patient being treated the results were encouraging but not definite after several months. In June 1946 sufficient streptomycin to treat 10 cases was received and $\frac{1}{2}$ gm. or 250,000 S. units were injected every three hours for four months in 8 of the patients. Unpleasant and even serious toxic effects were observed, the most frequent being vertigo with lasting deafness in one, anorexia, anaemia, loss of weight and low blood pressure, fever, headache and casts and blood cells in the urine due to renal irritations. The drug requires further purification. Improvement was noted but was not greater than that achieved with less toxic sulphonamides. It is too soon to judge of the value of streptomycin treatment. L. R. vers

FITE G. L. ERICKSON P. T. GEMAN F. & JOHANSEN F. A. Local Treatment of Leprous Ulcers with Crude Preparations of Streptomycin. *Internat. J. Leprosy* Cleveland, Ohio. 1947 Apr-June v 15 No. 2, 154-61 11 text figs & 1 fig on 3 pls

Crude filtrates of *Streptomyces griseus* of local manufacture have been tested on leprosy ulcers with promising results. The original paper should be consulted by those interested in the method of culture. The filtrate contained 28 to 40 microgrammes of streptomycin per cc. and was used by soaking layers of gauze with it and applying them to the ulcers with a protecting layer of rubber to prevent excessive drying. The gauze is soaked every twelve hours for a week and then renewed weekly until the ulcer is healed, provided that no irritation is produced. If erythema with vesiculation is produced, the filtrate

should be diluted 1 in 5 with boric acid. Thirty-six patients have been treated and in only one did toxic symptoms necessitate stopping the applications, and another patient objected to the bandaging. Notes of illustrative cases are given. They are divided into three groups. In group I, consisting of perforating ulcers of the sole of the foot, success was obtained in 18 out of 19, in mixed cases, in 11 of 14, and in the only lepromatous case treated. Sloughing varieties show most resistance to the treatment and complete healing was only obtained within two months in 45 per cent. Trophic ulcers respond best. Of the total cases, one-fourth healed in less than one month and 70 per cent in two months. The results are therefore satisfactory. Photographs of cases before and after treatment are recorded.

WILKINS, A J W. Schistosomiasis in Salisbury, S Rhodesia. *Pub Health* Johannesburg 1947, Nov v 11, No 11, 4-6 9-10

This paper was read to a Health Officials' Congress in Southern Rhodesia by the M O H of the capital city, Salisbury.

He gives figures from the health department files concerning African patients, showing that on single microscopic examinations 30 per cent of 13,000 urines and 8 per cent of 9,400 stools were positive for bilharzia eggs. He believes [probably rightly] that the true infection rate is much higher than this and goes on to discuss measures for its amelioration. Like most workers with primitive peoples he despairs of an immediate public response to the provision of sanitary facilities, although he notes that in Salisbury, where numerous conveniences have been provided there has been a considerable reduction in promiscuous fouling. He also feels that the numbers requiring treatment are too great for his department to be able to rely on mass treatment of infected people as a control measure. He has therefore set out to kill the bilharzial snails [he names

Physopsis globosa but it is not certain whether this species or *P. africana* is more important) in the water around Salisbury and he reports success with a copper-sulphate-bag method, as follows —

"The salt of which the larger lumps have been broken, is placed in a small bag of cloth mosquito netting, cheene cloth or organzine which is attached by string or wire to a stick. The bag is then dipped in and out of the water along the sides of the pool or stream particular attention being given to water in the vicinity of reeds or other grasses. In our experience it has been found that by moving along the bank fast enough to allow the bag to be submerged in the water and withdrawn immediately and for this to be repeated at approximately 1" to 18-inch intervals when the flow is not too rapid or very considerable in volume the concentration obtained has proved sufficient to kill 100% of the snails present.

[It must however be pointed out that this bag method is not a universal application. While no doubt satisfactory where river-banks are fairly level and well-defined or in ditches or irrigation canals, it is of little value in the treatment of "wild" river-courses, with their broken and irregular banks. The author himself points out that the bag method is being used in favourable conditions.]

He makes the interesting observation that it has been found possible to use his "anti-malarial gangs" on this snail destruction work a great saving in expenditure.

His work shows that it is apparently possible to protect a small area in an infected country when this is desirable because of the large concentration of people living in that area.

ZITO P. Tentativi di infestazione di molluschi nodranti con uova di *Schistosoma haematobium*. Osservazioni sulle uova ed azione di alcune sostanze su esse e sul miracidio. (Observations on the Infestation of certain Molluscs with *S. haematobium* the Effects of Different Substances on the Eggs and Miracidia. *Acta Med Italica*. 1947 Dec. — No. 12, 375-7

The English summary appended to the paper is as follows —

"The author describes the characters of the molluscs intermediate hosts of some trematodes which infest man — he reports on some negative attempts of infestation of molluscs (*Planorbis cornutus* Phase "Physa" fontalis *Hebertella termiculata*) with eggs of *Schistosoma haematobium* — he exposes some observations on the eggs of *Schistosoma haematobium* and its miracidium and on the action of some substances (cousm trypanflavine, penicillin) on them — cousm trypanflavine kill the embryo — penicillin has no effect on the time of opening of the eggs and on the miracidium.

COWPER, S. G. Observations on the Life-Cycle of *Schistosoma mansoni* in the Laboratory with a Discussion on the Snail Vectors of *S. mansoni* and *S. haematobium*. *J. Trop. Med. & Parasit.* 1947 Sept. v. 41, No. 2, 173-7. [14 refs.]

The author writing from the Liverpool School of Tropical Medicine, has succeeded in establishing strain 1 *Schistosoma mansoni* in a monkey after having infected strain 1 *Planorbis* boursieri with miracidia obtained from infected faeces of patients who acquired the disease in Uganda. These snails were from an Egyptian stock and the author also succeeded in infecting *Ambrosia palustris* the tropical American intermediate host. He describes the technique adopted, which was perfectly simple.

Bul nas forskalii (Ehrenberg) but has not found any living specimens. He also mentions a number of other snails which are not, so far as is known, concerned in human schistosomiasis.

Charles W. Brooks

GIAGIS B. & ARIZ, S. Treatment of Schistosomiasis. *Lancet*. 1948, Feb. 7 206-9 1 fig.

The authors have investigated the action of sodium antimony tartrate in the treatment of schistosomiasis, following the method of Alves and Blair with minor modifications.

The total dosage of (freshly prepared) sodium antimony tartrate was 1 gram for every 5 kgm. of body weight and was divided into six more or less equal doses, which were given on two successive days at 8 a.m., 11 a.m. and 2 p.m. Special precautions were taken to give the injection slowly. The drug was prepared in a solution of 1 grain in 1 cc., and out of 18 patients, 12 received the dose undiluted, but in 4 it was made up to 10 ml. with 5 per cent. glucose solution. All-glass "Record" and "Linn" syringes were employed.

The immediate reactions are described as rather severe and in some cases drastic, whether the drug was diluted or not. The commonest were cough, vomiting, tightness of the chest, pyrexia and pain in the arm or shoulder, sometimes pain in the joints, toothache, a metallic taste in the mouth, a sense of irritation in the bladder or peculiar chondriiform movements of the arms and legs. On the whole, the patients had no appetite and preferred to stay without food for the two days of treatment. They invariably looked ill and dreaded the injections. Out of 18 cases, 6 had a mild bradycardia after each injection. A minor drop in the systolic blood pressure was sometimes registered. Electrocardiographic records were made of every patient before treatment, at the end of the first and second day's treatment, and again within the following week. Changes in the QRS complex and T wave appeared at the end of the first day, becoming more pronounced as treatment proceeded. These changes were restored about the second day after treatment.

The haemoglobin percentage tended to rise during treatment and this was ascribed to haemoconcentration. All patients showed a loss of 1-3 kgm. in weight during the same period, but regained it within 10-14 days. In *S. haematobium* infections, the patients continued to show haematuria until the 10th day after treatment but by the end of the second week all testified to the relief of urinary symptoms. On the second day after the end of treatment all patients were still passing living ova; by the 23rd day any ova passed were dead, but in five instances they were passed continuously for eighty days. Observations on these ova appeared to indicate that although temporarily damaged by antimony some worms survive and, after a period of cessation of oviposition, recommence reproduction. Dead ova are best demonstrated by sedimentation methods. In this state they are wrinkled, distorted and smaller than normal.

The difficulties of application of the two-day treatment in large-scale campaigns are obvious, therefore 9 patients were treated with the same doses spread over a six-day period.

On the whole the reactions were fewer and milder. The urine was examined after the third injection, five days after the end of treatment and subsequently at weekly intervals. Three patients were passing ova on the 11th day and by the 33rd day living ova were detected in two.

The relapse rates in these two methods was 31 and 33 per cent. respectively. While admitting that the two-day treatment of Alves is an advance over the original method, the authors consider it to be too drastic to be useful in large-scale campaigns.

P. M. ALLEN-BALL

NESS, A T, BRADY, F J, COWIE, D B & LAWTON, A H **Anomalous Distribution of Antimony in White Rats following the Administration of Tartar Emetic.** *J Pharm & Exper Therap* 1947, June, v 90, No 2, 174-80, 1 fig

"Dogs and rats were injected with tartar emetic prepared from radioactive antimony. Antimony concentrations in the blood and tissues of rats were considerably different from those in dogs and, judged by available data, were also different from concentrations encountered in man, white mice, cotton rats, and hamsters.

"In white rats, the blood antimony is characterized by an increasing concentration beginning at 8 hours and lasting at least for 72 hours. This is in contrast to that in man and in the dog in which the concentration is decreasing to very low levels at these intervals.

"There is some indication that the antimony compound appearing in the blood of the white rat at later intervals is considerably less toxic to the rat than its tartar emetic precursor. It is suggested that results obtained in screening antimonial compounds in white rats be interpreted with caution until more is learned of the phenomenon."

LUTTERMOSER, G W **The Control of the Blood-Fluke Disease (Schistosomiasis) in Venezuela.** *Health & Sanitation Division Inst Inter-American Affairs Newsletter* Wash 1947, Oct (Schistosomiasis Number) 24 pp, 25 figs & 3 maps

This Newsletter is, no doubt, written largely for the non-medical reader, but its author is already well known for his work on the subject, and his description, based on his own experience, is comprehensive and most informative. The publication is a succinct account of control measures, and could hardly be bettered. Luttermoser himself has returned to the United States (he is a graduate of Johns Hopkins), but no doubt his methods will be continuously developed in Venezuela.

The area of schistosomiasis in Venezuela lies within a semicircle of 100 miles' radius, whose centre is at Catia La Mar, there are coastal foci and foci along the main drainage systems, and they involve a population of over one million. It has been estimated that there are more than 50,000 cases of schistosomiasis (*S. mansoni*) in the country. Diagnosis is made by faecal examination by skin test with extract of adult *S. mansoni*, and at post mortem examination. (JAFEE at the Hospital Vargas had found it to be the cause of death in 54 per cent of 2,461 autopsies, that it was present in 18 per cent, and that of those with the disease, 37 per cent died of it.) Treatment is given to infected persons at the various clinics, and tartar emetic and Fouadin are used.

Eradication of *Australorbis glabratus* (the snail host) includes the clearance of vegetation from irrigation canals, and the training or paving of the bed and banks of these canals, to increase the rate of flow. Water holes are filled in or drained and copper sulphate or carbonate, or freshly-slaked lime, are applied where they run near houses, so as to protect them from fouling. Latrines are constructed and the people are educated in their use and instructed in the mode of infection. The disease is most prevalent among the poorer people, and it is thought that general education may be a potent force in reduction of infection. An account is given of the various surveys made at Maracay, the El Valle river system and the Guarenas region. Snails occur in rivers where the current is slow and where there is much vegetation, optimum temperature is about 20°-26°C. Flooding may wash snails downstream into water holes or irrigation

canals. It was found (as had previously been known) that a standard sand filter will not hold back cercariae, but that standard chlorination of water if carefully controlled, will destroy them.

Snails are found in great numbers in watercress gardens, sugar-cane plantations and other similar cultivated areas. Watercress cultivation is a most important industry—the method adopted to eliminate the snails was to remove all vegetation from the beds (each about 1.5 square yards) and treat them with freshly slaked lime and dry them thoroughly in sunlight. The banks were built up and the irrigation inlets and outlets were strengthened. The snail eradication work was begun at the head waters and continued downstream, and the watercress gardens were mostly in the upper reaches. New plants were carefully washed in lime water before planting.

A reed is grown in these upper reaches, which is used for animal packs—snail control in these gardens consisted largely of drying every 3 months and applications of copper sulphate. Workmen are advised to wear rubber boots, and efficient latrines are provided.

The author thinks that control is possible by more extensive and intensive use of the measures discussed, but he places special emphasis on health education and sanitary improvement.

Charles W. Stocks

REEVES D. L. & KEER, R. W. *Schistosomiasis Japonica with Intracerebral Granuloma: Operative Removal with Recovery*. Report of a Case. *Arch. Neurol. & Psychiatry* 1947 Aug., v 58, No. 2 207-203 figs. [12 refs.]

In the literature on *Schistosoma japonicum* there are reports in only two cases of the successful surgical removal of intracranial granulomata attributable to this parasite. Both the patients made good clinical recoveries. A patient of the authors a soldier of 29 when serving in the south west Pacific area, developed diplopia, headache and recurring convulsive seizures with loss of consciousness, in January 1945. In August 1945 a detailed physical examination revealed little more than bilateral papilloedema slightly impaired stereognosis on the left side and some weakness of the left hand grip. The cerebro-spinal fluid was at a pressure of 430 mm. but was otherwise normal. Subsequently ventriculographic study showed displacement of the ventricular system to the left with similar displacement of the third ventricle. There was a noticeable filling defect in the posterior and temporal parts of the right lateral ventricle which was flattened and depressed. A diagnosis of an intracranial expanding lesion in the right temporo-occipital area was reached, and as the patient had a history of a minor head injury in December 1944 the origin was considered to be a subdural haematoma.

Craniotomy was performed in the right occipito-parietal region. The dura was tense, and, on opening it small whitish tubercles from a pin-point to a pin-head in size were seen on the surface of a tumour which was indurated and rubbery. This was removed piecemeal and was found to contain small calcified areas. The tumour was about the size of an orange and extended into the subtemporal area. It was thought to be an unusual type of glioma.

On pathological examination, many *S. japonicum* eggs were found in a granulomatous mass with large areas of caseous necrosis. There were scattered giant cells, and varying degrees of infiltration with eosinophils and with mononuclear phagocytic cells. On the surface of the tumour there was thickening of the leptomeninges, with increased vascularity and some leucocytic infiltration.

On further questioning, in view of the pathological diagnosis it was found that the patient had probably acquired his infection in Levant in October or November 1944. Examination of the stools failed to reveal the presence of ova. He was treated with courses of thiopurine and of antimony potassium tartrate.

and with potassium iodide by the mouth. The patient's recovery after the operation was uneventful, and in June 1946 he complained only of some general weakness and occasional headaches particularly on the right side and at the back of the head.

The authors conclude with a brief historical review of the discovery of Asiatic schistosomiasis, and a consideration of its causation, symptomatology and treatment. They point out that their case presented none of the expected symptoms and signs of the disease, and so the correct diagnosis was not suspected until revealed by the pathologist. The importance of the condition is apparent in view of the large numbers of United States troops who served in the south-west Pacific and other endemic areas.

VARTIAINEN, I & BASTMAN-HEISKANEN, L. On the Staining of *Diphyllobothrium* Ova. *Ann Med Intern Fenniae* 1947, v 36, No 3, 729-39 [11 refs]

"The ova of *Diphyllobothrium latum* behave differently in eosin solution. Some are stained red, while others remain colourless. This is true both of ova found in the excrements of worm carriers and of eggs taken from the tapeworm itself.

"The percentage of stained eggs is lowest in the first metres of the worm, but grows higher toward the end part of the parasite, and may then be as high as one hundred per cent. Correspondingly, the number of living larvae is highest in the first metres and very low in the last. The ability of staining undoubtedly means that the ovum is dead, and this may be regarded as indicating decreased vigour in that part of the parasite.

"In all, seventeen worms were examined in order to find out how far the ova were stainable in the different parts of the worm. In this respect, there were differences between the individual worms."

TOTTERMAN, G. Is the Broad Tape-Worm the Causal Agent of Hypochromic Anemia? *Ann Med Intern Fenniae* 1947, v 36, No 1, 185-90 [13 refs]

It is established, says the author, that *Diphyllobothrium latum* may cause typical pernicious anaemia in some of its carriers. In a far greater number, however, there is a "hyperchromic, or an almost normochromic mild anaemia" and these latter cases are cured by a vermifuge and should therefore be considered as being due to the tapeworm. Opinions vary about the relation between hypochromic anaemia and this tapeworm. The history of these questions is briefly discussed with references to the literature.

The author himself studied 43 cases, 34 females and 9 males, with hypochromic anaemia and *D. latum*, most of them had other diseases as well. Thus, 23 had acute infections which included pneumonia, exudative pleurisy, pyelitis, acute polyarthritis and acute nephritis. Three patients had chronic infections and 2 had tumours. It is, the author says, "highly probable" that in these cases the complicating diseases and not the worm caused the hypochromic anaemia. But 10 patients had no complicating diseases. Nine of these had "anaemia achylia simplex" and one had chlorosis.

The author discusses these, his general conclusion is that no single case of hypochromic anaemia in his series was definitely improved by a vermifuge.

alone that the presence of *D. Latum* does not seem to impede the spontaneous improvement of the blood picture after an infection or to check the effect of iron in a post-haemorrhagic or an essential hypochromic anaemia and that broad tapeworm anaemia and hypochromic anaemia are not causally connected. This is probably the reason why the combination of broad tapeworm and hypochromic anaemia is relatively infrequent especially in comparison with the frequency of hyperchromic anaemia and broad tapeworm. [See also this *Bulletin* 1948 v 45 97 188, 260]

HIRVONEN M. Observations throwing Light on the Pathogenesis of Pernicious Tapeworm Anaemia. (*Ann Med Intern. Fennic.* 1947 v 36, No. 1 53-65 4 figs. [11 refs.])

Dephylobothrium latum is the author says very common in Finland, yet people infested with it seldom have anaemia. EHRESTRÖM, quoted by von Bonsdorff cited below calculated that only 1 patient in 5 000 to 10 000 is ill with tapeworm anaemia but SEPPÄS (*Duodecim* 1927 v 43, 101) estimate is 1 in 650 and TÖTTERMAN'S 1 in 113 to 1 in 383. SALTMAN (*Acta Med. Scand. nava* 1924 Suppl. 7 p. 268) and VON BONSDORFF (this *Bulletin*, 1940 v 37 215 216 *ibid* 1944 v 41 583 594 and *Nordisk Med* 1941 v 1, 2877) ascribe this incidence either to an abnormal character of the worm or to a constitutional disposition of the host. The latter explanation was supported by SCHRAUMAN (quoted by von Bonsdorff and Saltman) but has not been proved. The present author describes one case which in his opinion, "indicates very clearly, that the abnormal character of the worm decidedly influences the genesis of tapeworm anaemia. This case was a woman aged 23 whose anaemia disappeared after administration of filicium, which failed to remove the whole worm. She had no anaemia when she returned 1½ years later for further treatment for removal of what the author considered to be the same tapeworm. He suggests that the anaemia in this case may have been caused by some disease of the tapeworm and that the anthelmintic may have cured this, so that the patient's anaemia disappeared.

Three other patients are also discussed all of whom had free HCl, so that pernicious anaemia was absent. In all three cases blood regeneration ceased after the worm cure and only continued when liver treatment was given. Examination of these cases 4 8 and 7½ months respectively after cessation of the liver treatment showed that all were completely healthy. The author discusses these cases in relation to the view that *D. latum* destroys all the anti-anaemic liver factor at the patient's disposal and suggests the alternative hypothesis that the worm poison has a paralyzing effect upon the blood forming organs, the bone-marrow and the liver which were strong enough in these 3 cases to begin regeneration of the blood but not strong enough to complete this without the help of liver treatment.

BACHMUT, A. Situation de l'ankylostomose au centre marse de Khouribga en 1945. (The Ankylostome Problem in the Khouribga Mines in 1945.) *Bull Inst. Hyg. Maroc* 1945 v 5 75-83

In the phosphate mines at Khouribga in 1908 in two sections parts I a mine 68.68 per cent and 40.51 per cent of the workers respectively had ankylostome infection. It was heavy in 8.9 and 1.7 per cent, medium in 33.37 and 13.68 and light in 26.68 and 25.65 per cent. The number of healthy workers infected within 6 months was 65.93 and 20.17 per cent respectively.

As a result of prophylactic procedures by the end of 1941, there were no heavily infected workers, only 21.7 and 16.1 per cent of lightly infected carriers and the chances of contamination in 6 months were reduced to 9.9 and 3.6 per cent respectively.

The remaining 109 lightly infected carriers in the two *recettes* had only an average of 10 eggs per ml of stool and were healthy. During the next four years, their number was reduced to 70, 30, 13, and 6 successively while the numbers of the workers had risen from 885 to 3,132. By 1945 no parasite-free workers became infected after working 6 months in the mines.

This improvement was achieved by two procedures: (i) the treatment of all the medium and heavy carriers, and (ii) the construction of double trench latrines, 1.50 metres wide by 3 metres deep, at various points in the mines so that no worker had to go more than 400 metres to use one.

The latrines and the surrounding earth were periodically disinfected with cresyl and chloride of lime, and the latrines were abandoned long before the contained faecal matter reached the level of the galleries.

For sterilizing the carriers, the author found *Essence de Niaouli* and oil of chenopodium quite useless, and male fern, thymol and carbon tetrachloride very inadequate. Tetrachlorethylene was reliable, he gave it in 1-gramme capsules for three days, 3 grammes on the first day, 4 grammes on the second and 5 grammes on the third, followed three hours after the last dose by 40 grammes of sulphate of soda. By this means he obtained expulsion of worms in 100 per cent, complete removal of infection in 87, and partial removal in 13 per cent of those treated.

The author used the book on ancylostomiasis by GARIN, ROUSSET and GAUTHIER for constant reference, and adapted their teaching to the local conditions.

PANTOJA, W. P. & BASSÈRES, M. S. Verminoses — Tratamento em massa pelo hexyl-resorcinol [Mass Treatment of Worm Infections by Hexyl-Resorcinol] *Rev. Serviço Especial de Saúde Pública* Rio de Janeiro 1947, July, v. 1, No. 2, 251-60.

The English summary appended to the paper is as follows —

"1 A total of 7,341 people, including all age groups from 2 years up were treated in mass treatment campaigns in labor camps and small villages in the states of Espírito Santo and Minas Gerais, during 1944 and 1945, using the hexyl-resorcinol 'cristoids'.

"2 In a group of 117 children, apparently healthy, living in a leprosarium preventorium, in which the mean egg count (Stoll-Hausheer) showed 2,630 hookworm eggs per cc. two treatments by the standard dosages showed a reduction of 85.2 per cent from the mean number of eggs found in the first examination. It is emphasized that in spite of the relatively low reduction of hookworm eggs, after two treatments, the hexyl-resorcinol should be the drug employed in rural areas where there is a high prevalence of associate hookworm and ascariis infections. The mass treatment campaign is the method of choice and should be built around the drug, to take full advantage of its atoxicity and remediate [sic—? compensate for] its apparently low reduction of hookworm following a single treatment.

"3 Except for extremely rare manifestations of slight abdominal discomfort, and some allergic reactions, probably due to dead ascariis, no untoward symptoms were observed."

- i. DAVIDSON A. G. BARON BENNE & WALKER, M. Factors influencing Reagin Formation in Experimental Human Sensitization to *Isurus* *lambrocoides* Antigen. I. Influence of Chronic Infection (Tuberculosis) on Rate of Sensitization. *J Allergy* 1947 N. v., v 18, No. 6, 359-64, 3 figs.

- iii. — — — & — — — III. The Influence of Race as a Factor in Rate of Sensitization with further Observations on the Sex Factor. *Ibid.* 373-80, 3 figs.

This is a study on allergy and the relation to *Isurus* infection is not considered.

i. FILLBORN and HIAUTW [this *Bulletin* 1930 v 27 956] and others have shown that sensitization of the skin to *Isurus lambrocoides* could be induced in man. The antibodies responsible for the immediate skin reactions in *Isurus* hypersensitiveness are atopic reagins.

In these studies the extract was prepared from *Isurus lambrocoides* (pg). The worms were first washed in water afterwards in toluol. "They were then covered with a slight excess of buffered saline and with a layer of toluol. This was allowed to stand at room temperature until most of the worms had disintegrated. The material was paper-filtered and sterilized by Seitz filtration on June 2, 1933. The extract was bottled, covered with a layer of toluol, and stored in the ice box. On September 3 1935 it was again passed through a Seitz filter. At this time the total nitrogen content determined by the macro-kjeldahl method was 5.3 mg. N per ml. From this stock material, proper dilutions for use in this study were made."

The experimental subjects were selected by giving a test dose of 0.025 ml. of an extract containing 0.1 mgm. of N per ml. Only persons giving a negative reaction were used. Sensitizing doses of 0.1 ml. were given at intervals of one week until complete sensitization was effected, or 12 doses had been given. A positive reaction was indicated by the formation of a weal and erythema.

About one third of the persons given the test dose showed positive or doubtful reactions and were excluded from the experiment.

The sensitization developed in the rest at a variable rate. 19 per cent became sensitive at the time of the third sensitizing dose (S_3), 54 per cent. at S_4 , 81 per cent at S_5 , and 92 per cent. at S_{12} .

Chronic tuberculous infection was not a factor influencing the rate of development of sensitivity but sensitivity developed more rapidly in males than in females. The number of positive reactions was higher by about 25 per cent. in males than in females between the S_3 and S_5 but the final percentages, i.e. at S_{12} , were equal in the two sexes.

ii. The observation made in the earlier investigation that active sensitization to *Isurus* antigen develops earlier in the male was confirmed, and it was incidentally indicated that there is earlier sensitization to the antigen in the Negro race than in white persons.

iii. Further confirmation was obtained of the earlier sensitization to *Isurus* antigen of negroes compared with white persons and males compared with females. There was no correlation between the rate of sensitization and the natural sensitivity in the four population groups which was undoubtedly but not demonstrably associated with present or past helminthic infection. There was no correlation between rate of sensitization and age. L. E. Vajner

FRANKS, M B, CHENOWETH, B M, Jr & STOLL, N R Reactions of Natives of Okinawa and of American Personnel, to Skin Tests with Test Antigen prepared from Microfilariae of *Dirofilaria immitis* *Amer J Trop Med* 1947, Sept, v 27, No 5, 617-32, 3 figs & 2 graphs [18 refs]

After a brief review of the relevant literature, the authors describe skin tests done from July to October, 1945, on the island of Okinawa. Antigens were made from the adults (females only) and microfilarial larvae of *Dirofilaria immitis* of the dog and from *Ascaris lumbricoides* obtained at necropsies in a Guam hospital. For the methods of making these antigens, the paper must be consulted. *Trichinella spiralis* antigen was supplied by the National Institute of Health. This and saline containing 1/10,000 merthiolate (used to preserve the other antigens) were used as controls. References are given to the methods of counting the helminth eggs in faeces, and the number of microfilariae.

Skin tests were done on more than 400 patients in two natural groups. Group I were service personnel. Sixty of them, stationed on Guam, had not previously been outside the U S A and were not known to have been in areas in which filariasis is endemic, fifty-three had no intestinal helminths, 7 were lightly infected with these. Group I included also 9 patients with a clinical diagnosis of filariasis. Group II consisted of natives of the endemic area of Okinawa considered to be fairly representative of the island's population.

Details are given of the method of doing the skin tests and other examinations of the patients. Examination of a random sample of 677 Okinawans showed that 26.6 per cent had circulating microfilariae and that 57 per cent of 259 Okinawans with this degree of microfilaraemia had physical signs attributable to filariasis. A table illustrates the increased incidence of physical signs with increasing ages, a fact which was considered in the interpretation of the skin tests. Diagnosis was conservatively made on involvement of lymph nodes and channels, the extremities and the scrotum and may have placed the incidence of physical signs too low. Only 8 persons examined (rather more than 1 per cent) had elephantiasis, which was no functional handicap to 4 of the 8. As only 20 other cases of elephantiasis were seen and only one of these was multiple, the usual assumption that filarial infestation and elephantiasis go hand in hand was not confirmed in Okinawa. Combined blood and chemical studies indicated a demonstrable incidence of filariasis in Okinawa of 65 per cent and probably this is considerably higher. The authors concluded, in fact, that they were justified in considering all Okinawans, except very young infants, to be infected.

No intact adult worms were found, but the nocturnal periodicity of the microfilariae and examination of stained smears of them showed that the infecting species was *W bancrofti*. Microfilarial counts of blood drawn between 8 and 10 p.m. from 180 patients varied from 1 to 23,000 microfilariae per ml, 80 per cent of cases had 1,000 or less per ml and only 6 per cent had 4,000 or more per ml. Positive examinations for microfilariae increased significantly with age, especially when children of 6 to 15 years (19 per cent) were contrasted with adults aged 46-74 years (34 per cent), the corresponding figures for incidence of physical signs in patients with microfilaraemia being 38 per cent and 95 per cent and in patients without microfilaraemia 40 per cent and 73 per cent. There was no positive correlation between the numbers of circulating microfilariae and either the age of the patients or the degree of clinical filariasis. Of the 8 patients with elephantiasis, 4 had circulating microfilariae but in 3 of these the elephantiasis was minimal (*cf* above).

For details of the results of the skin tests the paper itself must be consulted. An important net result was the confirmation of the conclusion of earlier workers that an antigen made from microfilariae of *D immitis* has a limited use as a diagnostic aid in filariasis. It is more specific in the sense that fewer false

mode of action of filaricides the trial and error method of approach seemed the most commendable one

In experiments with dogs, heavily infected animals were considered poor risks for treatment, since large numbers of worms, if killed quickly and simultaneously may produce an embolus in the pulmonary artery and kill the dog. On the other hand, dogs (as well as cotton rats) with low initial microfilarial counts are unsatisfactory for assay purposes. These animals were used only in testing compounds which had shown activity in the cotton rat, in dosages derived from experience of their tolerance in cotton rats.

Three criteria were used in determining the effectiveness of new compounds against *Dirofilaria* in dogs, (1) a rapid and sustained reduction in microfilariae, (2) presence of dead worms in the terminal blood vessels within the lungs at autopsy, and (3) improved physical condition of the dogs.

Of 517 organic non-metallic compounds which were tested, several types showed activity in the cotton rat, but the best balance between activity and toxicity was found in the piperazines, administered orally or intraperitoneally. Detailed results of the effects produced by piperazine derivatives are presented in subsequent papers [see below]

J J C Buckley

HEWITT, R I, WHITE, E, WALLACE, W S, STEWART, H W, KUSHNER, S & SUBBAROW, Y. Experimental Chemotherapy of Filariasis. II Effect of Piperazine Derivatives against naturally acquired Filarial Infections in Cotton Rats and Dogs. *J Lab & Clin Med* 1947, Nov, v 32, No 11, 1304-13

The authors found that several members of the piperazine group produced precipitous reductions in the microfilarial counts in cotton rats after various oral or intraperitoneal doses. Of these derivatives, 1-carbethoxy-4-methylpiperazine hydrochloride (compound 180-C) was consistently effective and was at first used as standard in the treatment of 81 cotton rats. Detailed results of this series are tabulated. Compound 180-C was markedly effective against microfilariae in cotton rats in well tolerated doses but its effect against adult worms was not as promising. In dogs, the dosages which reduced microfilariae had adverse effects on the dogs themselves. However, another compound 1-diethylcarbamyl-4-methylpiperazine hydrochloride (84-L) was subsequently chosen as standard, and was effective in reducing microfilariae in doses as low as 3 mgm per kilogram in cotton rats, and produced no toxic effects in dogs, in therapeutic doses. Furthermore, frequent administration of compound 84-L resulted in the death of a large proportion of adult worms in cotton rats.

A detailed report on this compound is given in another paper in this series [see below]

J J C Buckley

HEWITT, R I, KUSHNER, S, STEWART, H W, WHITE, E, WALLACE, W S & SUBBAROW, Y. Experimental Chemotherapy of Filariasis. III Effect of 1-Diethylcarbamyl-4-Methylpiperazine Hydrochloride against naturally acquired Filarial Infections in Cotton Rats and Dogs. *J Lab & Clin Med* 1947, Nov, v 32, No 11, 1314-29

Detailed data are presented showing the effects produced by 1-diethylcarbamyl-4-methylpiperazine hydrochloride (compound 84-L) on

natural infections with filarial worms of cotton rats and dogs. The structural formula of compound 84-L is given below —

Two hundred and twelve cotton rats and twenty five dogs were used in testing this compound against both the microfilariae and the adult filariae. After oral or intraperitoneal treatment of filaria infected cotton rats at doses ranging from 3 to 100 mgm. per kilogram the microfilarial count dropped suddenly within 24 hours and became negative or remained very low as long as treatment continued. *In vitro* experiments led to the conclusion that the compound acts directly on the microfilariae in the blood. The rate of disappearance of microfilariae in dogs is not so rapid as in cotton rats but in one to two weeks over 90 per cent. generally disappear.

The effect of the compound on adult filariae in cotton rats varied with (1) the amount of drug given, (2) the frequency of the dosage and (3) the number of days lapsing from cessation of treatment to autopsy. Of 150 rats treated with 10 mgm. per kilogram at least twice daily 72 per cent. showed either some or all adults dead at autopsy but dosage three times daily was shown to give more consistent results.

In general animals treated with less than 10 mgm. per kilogram did not exhibit as many dead worms at autopsy as those treated with 10 mgm. or more per kilogram. Usually the longer the period between cessation of treatment and autopsy the fewer live worms were found on autopsy. Oral and intraperitoneal treatment of dogs with compound 84-L was encouraging in that doses necessary to affect the microfilarial counts and in some cases, to affect the adult worms, did not produce signs of severe toxicity. Detailed data of the results of treatment of 25 filaria infected dogs are tabulated. Although the optimum treatment schedule has not yet been determined it appears that frequent administration of the drug for several weeks is desirable.

VAN HOUT L. HENRIARD C. PERL E. & WANSOV M. Sur la chimiothérapie de l'Onchocercose (Note préliminaire). The Chemotherapy of Onchocerciasis: Preliminary Note. *A. Soc. Belg. de Méd. T. p.* 1947 Mar 31 v. 27 No. 1 173-7

Since 1944 the authors have systematically tested various drugs for curative action in onchocerciasis — oil of chenopodium, eucalyptine, thymol, commercial pyrethrins, antimonials, atarsin and Trypanosan. Only the last gave indication of usefulness and its effect was transient. This, however, encouraged the authors to try the organic trypanocidal drugs especially Antryptol (or Belganyl). In 1942, moreover 14 volunteers for (successful) experimental infection with *O. volvulus* also volunteered for infection with trypanosomes and were treated

with Antrypol, more than two years afterwards they were found free, not only from trypanosomiasis, but also from onchocerciasis

The authors have treated with Belganyl a series of patients suffering from onchocerciasis. At first they gave two doses, each of 2 grammes, each week, but after the second or third injection there was often an intense reaction, with fever, severe articular pains, pruritus about the skin lesions, and massive exfoliation, and pain in the onchocercal tumours. Patients with eye involvement showed conjunctival reactions. Later the authors found that a total dose of 7 grammes, given at the rate of 1 gramme each week, was usually enough to cause disappearance of microfilariae and macrofilariae within 1-2 months, a total dose of 10 grammes appeared always to be successful. Dead adult filariae, containing dead and degenerated embryos, are found in the tumours. The authors found appreciable amounts of the drug in cysts, even 6 months after the last injection.

Fuller details of this work are to be published later

Charles Wilcocks

STRYKER, W. A. The Intestinal Phase of Human Trichinosis. *Amer J Path* 1947, Sept, v 23, No 5, 819-27, 4 figs on 2 pls [27 refs]

There are few records of the discovery of adult *Trichinella spiralis* in the intestine of man. The author gives 7 of these. A few of them are confirmed by microscopical examination. Persistence of adult *Trichinella* in this situation has been recorded for 30 days, but not longer. Work on trichiniasis of experimental animals, especially that done by ROTH (*J Parasitology*, 1938, v 24, 225), suggests, however, that the female *Trichinella* produces larvae for about 6 weeks.

The author reports on a man, aged 35, who had acquired trichiniasis from raw pork sausage prepared from a hog raised and butchered by himself. Other members of his family were also infected and his daughter, aged 8, died. The patient's wife and the family doctor said that raw pork had been eaten once only, the father and daughter having eaten more than the others did.

The father had diarrhoea, marked muscular pain, fever and terminal respiratory distress. There were physical and electrocardiographic signs of myocardial damage and neurological abnormalities which suggested cerebral damage. Death occurred 54 days after eating the pork. Adult male and female *Trichinella* were found microscopically in many sections of both the large and small intestine, being more numerous in unopened portions of the intestine, whose contents were not disturbed. Most of the females contained larvae. The nematodes were free in the lumen or embedded in the mucosa, one having penetrated as far as the *muscularis mucosae*, though none penetrated further than this. Often one end was in the mucosa, the remainder projecting into the lumen. Most often the "uterine area" of the *Trichinella* was embedded in or in contact with the mucosa which showed no significant cellular reaction around the worms, lymphocytes or plasma cells and eosinophils being found elsewhere in the mucosa at a distance from the worms and also in control cases not infected with *Trichinella*. In the intestine granulomatous infiltration, haemorrhage or foci of necrosis were not found, but the infestation of skeletal muscles was unusually heavy, larvae being present even in the cremaster muscle of the spermatic cord. Single muscle fibres contained as many as 3 larvae at the level of a single section. Some larvae were still straight, but most were coiled and cyst formation had begun. Many muscle fibres showed hyaline degeneration and between them there was a heavy cellular infiltration of mononuclear macrophages, lymphocytes, plasma cells and many eosinophils. A few foci were purulent. Dr S. E. Gould found 2,677 larvae per gramme of diaphragmatic muscle, which is one of the heaviest infestations known. The

heart and brain showed typical trichinosis myocarditis and encephalitis, larvae being found in both these situations. Photomicrographs illustrate this.

The author briefly discusses the resistance of various hosts to *T. spiralis*, suggesting that man is relatively susceptible and that the intestinal phase of the first infection may be prolonged, because there is no acquired resistance and that infection with relatively large numbers of larvae may also prolong the intestinal phase. These were features of the case reported and they are correlated with the fact that the period of persistence of the adults in the intestine was one of the longest ever reported and larvae were still being released 54 days after infection. Persistence of the intestinal phase means persistence of the myocarditis and increased severity and duration of the myocarditis and encephalitis death during the acute phase being usually due to lesions of the heart and central nervous system. These organs are affected only by migrating larvae which do not encyst in them so that inflammation of these organs subsides when the larvae move on. Thus in the case reported, larvae were found in the heart and brain, in both of which there was granulomatous infiltration.

Attempts to remove the worms from the intestine are therefore important. The author thinks anthelmintics are of little use and recommends (with references to the literature) purgation, attention to the patient's fluid balance and general condition and administration of immune and convalescent sera which may affect the larvae and reduce the number of adults. *G. Lapage*

DEFICIENCY DISEASES

HANAFY M. The Subacute Subnutritional Syndrome in Infants. *J. Roy Egyptian Med Ass.* 1947 Sept v 30 No. 9 440-50 18 figs. on pls.

Malnutrition in infants may present numerous different clinical pictures. The author believes that these are all stages in the development of a single syndrome. This conclusion is based on the study of 197 cases, mostly between the ages of one and three years all of whom had been fed for some months on a diet consisting only of rice or cereal water.

Four grades of severity are distinguished.

1. Weight loss up to 15 per cent. with or without signs of riboflavin deficiency.
2. Weight loss from 15 to 30 per cent. with irritability, diminished reflexes, and a dry inelastic skin. Oedema may be present.
3. Weight loss from 30 to 50 per cent. In some cases there are pellagrous skin lesions, in others an enlarged tender liver (pre-ascitic stage of cirrhosis).
4. Weight loss more than 50 per cent. Cirrhosis of the liver may be present with or without pellagrous lesions.

Only the most severe grades are described in detail. The picture corresponds closely to that of kwashiorkor in West Africa or infantile pellagra in South Africa. Some additional features were found. Bronchectasis was present in 5 per cent of cases. Carpal pedal paresthesia suggestive of beriberi was sometimes observed, although the blood calcium did not fall below 8 mgm. per cent. In some cases the bones showed a definite clinical picture of rickets. The stools sometimes contained blood, pus and mucus. Three cases resembled Von Jaksch syndrome with pleiomegaly, leucocytosis and anaemia.

Early cases responded to treatment with high protein diet and vitamins. In the most severe grades, nicotinic acid and vitamin B were ineffective.

In agreement with the observations of GILLMAN [this *Bulletin*, 1946 v 43, 237] administration of one factor alone made the general condition worse. Good results were obtained with vitamin B complex (the form is not stated) and with crude liver extract and best of all with these two together. Parathyroid hormone, first tried because of tetany, was also found to enhance the action of liver extract.

No figures of mortality rate are given, and little is said of prognosis except for the important point that the prognosis is not affected by the presence or extent of either oedema or pellagrous skin lesions.

Analysis of the symptoms and of the response to treatment suggests that the disease is the result of a multiple deficiency—of protein, vitamin B complex, and vitamins A, C, and D. To these may perhaps be added deficiency of unidentified factors present in liver extract. In late cases there may be a change in endocrine function, which can only be restored by replacement therapy with hormones.

[This paper is illustrated by many striking photographs. It is the first description of the kwashiorkor syndrome that has appeared from Egypt as such; it is important in view of the earlier suggestion that the disease occurs only in children of negro stock. In Egyptians, the syndrome appears to be unusually well-developed, covering almost the whole range of known deficiency states, since in some cases there was evidence of rickets and of vitamin A deficiency. These conditions are not part of kwashiorkor as it occurs in the tropics although they were present in some cases described by Gil in Mexico.]

In kwashiorkor the liver is typically fatty. Dr Hanafy's mention of cirrhosis with ascites raises interesting speculations. It is to be hoped that the results of post-mortem examinations will be published.]

GLUSMAN M. The Syndrome of " Burning Feet " (Nutritional Melalgia) as a Manifestation of Nutritional Deficiency. *Amer J Med* 1947 Aug v 3 No 2 211-23 [50 refs]

Ho, T. T. Een klinische observatie omtrent beri-beri onder het werkvolk in Tandjong-Priok in de Japanse bezettingstijd [Clinical Beriberi in Batavia Port during the Japanese Occupation] *Med Maandblad* 1947, Dec, No 17, 326-31. English summary.

This investigation relates to the examination of 1,000 recruits for work in the harbour of Batavia and not to applicants for admission to hospital. Already this labour population, after 9 to 12 months of Japanese occupation, showed bodily deterioration. Out of the thousand coolies examined 157 were found suffering from severe beriberi with serious cardiovascular symptoms, and large numbers suffered from slighter degrees. It was especially noteworthy, and by previous standards the reverse of expectation, that 150 out of the 157 showed dry beriberi and only 7 wet beriberi. This leads the author to ask whether dry beriberi is not explainable as a partial thiamin deficiency and whether there is present in thiamin an anti-oedema factor. The clinical signs of dry beriberi are given in detail and it was noted that the calf muscles were neither swollen nor painful, reflexes were heightened, there might even be clonus, and the patellar and tendo achillis reflexes were especially marked. Rapid response to treatment with thiamin is illustrated by reference to 14 specially selected cases.

A general summary of the deductions made is presented as follows. In place of the classical beriberi triad of (1) oedema, (2) heart and vessel symptoms, (3) polyneuritic degeneration, the author gives the following description—

Anæmin-deficiency leads to degenerative changes of peripheral nerve twigs, chiefly restricted to two regions, those of (a) the peroneal nerve and the tibial nerve (b) the vagus nerve and vasomotor twigs. The predominance of the lesions in one or other or both of these two regions represents the clinical distinction between wet and dry beriberi."

SPRUE

FOURMAN L. P. R. The Chylomicron Count in Normal Subjects and Patients with Sprue. *Trans. Roy Soc Trop Med & Hyg* 1948, Jan., v 41 No. 4 537-44 [10 refs.]

After a fatty meal, the serum has a characteristic milky appearance, and under dark-ground illumination numerous fine particles less than 1μ in diameter are seen in a state of Brownian movement. These chylomicrons consist of neutral fat with an outer layer of globulin. Particle counts are made on a small drop of serum spread out by pressure between slide and coverslip. They are estimated in terms of the number of particles per standard field.

In an investigation on fat absorption in sprue, counts were made before and after a meal of 200 ml. of homogenized evaporated milk containing 18 gm. of fat. Chylomicron counts in individual cases were compared with the percentage fat absorption on a controlled diet and with blood fat and glucose tolerance curves. Eighty-seven curves were constructed on data from 28 patients with sprue and these were compared with eighteen curves on seven normal subjects. With a meal containing 18 gm. of fat the peak counts in normal persons ranged between 100 and 270 particles per standard field. The chylomicron curve in normal persons increased and diminished when more or less fat was given, suggesting that they do at least represent one form of absorbed fat. On the other hand, low curves were produced in normal persons by giving calcium lactate with the meal. In fat balance experiments calcium lactate did not produce steatorrhoea. When flat chylomicron curves returned to normal with clinical improvement there was no corresponding diminution in the steatorrhoea. Chylomicrons were shown to represent a variable fraction of the absorbed neutral fat in the serum. In untreated sprue low curves were found in about half the patients examined. After 2 or 3 weeks of parenteral liver therapy patients whose curves had been low gave normal curves.

It is concluded that a small proportion of the total fat is absorbed without splitting as finely emulsified fat.

Whilst all patients with sprue have a defective absorption of split fat only some show impaired neutral fat absorption as judged by the chylomicron count. Failure to absorb neutral fat is more common in the severe cases and responds to liver therapy.

SPIES, T. D., GARCIA, L., FREY, G., STONE, R. E., MILANES, F., BRADENBURG, R. O. & ARAMBURO, T. Further Observations on the Specificity of the Folic Acid Molecule. *Blood* 1948 Jan. 3 No. 1 121-8 9 figs.

Methyl folic acid, N-(4-(4-quinazolinyl)amino)benzoyl-L-glutamic acid, the Mg salt of formyl pteroyl glutamic acid, the Mg salt of formyl pteroyl aspartic acid, oxyfolic acid and pteronic acid have been studied as to their effect on blood regeneration in selected cases of idiopathic pernicious anemia, nutritional macrocytic anemia and tropical pruritus. In the amounts administered only the Mg salt of formyl pteroyl glutamic acid was effective.

in producing reticulocytosis and an increase in red blood cells, hemoglobin, white blood cells and platelets and it was not as effective per unit of weight as was folic acid per se. Presumably this compound is slowly changed into folic acid in the body. It is of special interest that the Mg salt of formyl pterotic acid (*Streptococcus lactis* factor) was negative in producing hemopoiesis. These observations show the very great specificity of the folic acid molecule.

DARBY, W. J., JONES, E. WARDEN, H. F. & KASER, Margaret M. The Influence of Pteroylglutamic Acid (a Member of the Vitamin M Group) on Gastrointestinal Defects in Sprue. A Study of Interrelationships of Dietary Essentials. *J. Nutrition* 1947 Dec 10 v 34, No 6 645-60, 5 figs (1 coloured) [43 refs]

Patients with the complete sprue syndrome may exhibit remarkable combinations of deficiency states. Some of these manifestations are: loss of weight (caloric deficiency), hypoproteinaemia (protein deficiency), petechiae (vitamin K or C deficiency), night blindness and xerosis conjunctivae (vitamin A deficiency), hypocalcaemic tetany and osteoporosis (vitamin D and calcium deficiency), and pancytopenia (vitamin M deficiency). In many cases these deficiencies may be classified as latent or potential.

With the demonstration of the activity of pteroylglutamic acid (PGA) [folic acid] in sprue patients it has been indicated that this vitamin exerts a favourable influence upon the gastro-intestinal abnormalities as well as upon the anaemia. In this paper additional evidence is adduced that PGA does so.

Six adult patients were under observation and all demonstrated the diagnostic criteria. The sole specific drug administered was synthetic PGA in doses of 5 mgm daily by the mouth or 15 mgm intramuscularly, except in one patient in whom this was preceded by 10 days' therapy with pteroyltriglutamate. During treatment one was on a milk-free diet but the remainder were on a regular ward diet.

During each relapse the patients complained of glossitis and all showed atrophy of lingual papillae. Subjective relief of glossitis resulted and the commencement of regeneration of papillae was evident within 3 days to one week. In relapse the same succession of events took place. If the appearance of the tongue is an indication of the state of the gastro-intestinal tract then it can be inferred that this vitamin exerts the same beneficial action on the mucosa.

In all instances cessation of diarrhoea was observed within a period of 3-9 days from the beginning of PGA therapy.

The minimum gain in weight varied from 6 to 45 pounds. The impression gained is that the weight changes were the result of increased appetite and better absorptive capacity of the gastro-intestinal tract.

A typical blood count curve (oral administration) there was a definite return to within the normal type of curve within 11 to 30 days after the institution of therapy. It is permissible to suggest that PGA assists the permeability of the gastro-intestinal tract to glucose.

The control of fat intake of patients is difficult. Observations on the effect of PGA on fat tolerance were limited by excessive determination on a large patient load. In a few cases (11 of 24) a marked increase of tolerance was obtained. It is probable that the effect of PGA on fat tolerance did not extend that obtained in the above mentioned group.

A study of the effect of PGA on the blood picture has indicated that the haemoglobin level is raised and the haematocrit value is increased. The effect of PGA on the blood picture was not studied in detail in this paper.

Vitamin A absorption determinations after an oral dose of 200,000 I.U. have shown that improved absorption had taken place in 2 out of 4 remissions studied. The hypoprothrombinaemia in sprue is attributed to deficiency of vitamin K. Two patients with hypoprothrombinaemia, before PGA therapy became normal during remissions.

The decrease in serum tocopherol (vitamin E) concentration during a sprue relapse as well as an increase after PGV administration are shown by graphs. There is a contrast between concentrations of fat-soluble vitamin E in patients with sprue and in those with pernicious anaemia.

X-ray changes of the so-called deficiency pattern type are present in sprue. In 3 out of 4 follow up films in remissions induced by PGA, a definite improvement in the pattern occurred.

The observations may be interpreted as indicating that the primary defect in sprue is a deficiency state which is corrected by PGA. The numerous interrelationships of PGA with other vitamins and food factors are a remarkable clinical example of similar relationships of foodstuffs in man and closely resemble the multiple deficiency states in the sulphonamide-treated rat.

As many cases of chronic sprue undoubtedly develop irreversible changes in the gastro-intestinal tract, and as degenerative changes in the intrinsic nerve plexuses have been demonstrated, it is improbable that they can be restored. Therefore the persistence of some degree of malfunction may be expected despite therapy.

Any disease which produces malabsorption from the gastro-intestinal tract may resemble the sprue syndrome and it is to be expected that PGV will be ineffective in the treatment of any disease which does not result from a deficiency of this vitamin. This factor should enable clinicians to separate the different clinical conditions which are loosely grouped together as the sprue syndrome. Regarding the possible synthesis of vitamins by the bacterial flora of the gastro-intestinal tract it has been observed that during PGV therapy a normal flora has been re-established in sprue. It is obvious that much more careful studies will be needed to define the relative rôles of altered gastro-intestinal absorption, metabolism and gastro-intestinal synthesis in the pathogenesis of the manifold deficiencies observed in sprue.

HAEMATOLOGY

SPIES, T. D., GARCIA LOPEZ, G., STONE, R. E., MILLER, F., TOCA, R. L. & ARASHIRO, T. Treatment of Nutritional Macrocytic Anaemia with Synthetic Folic Acid. *Lancet*, 1948, Feb. 14, 236-41, 2 figs.

Two important advances have been made recently in the discovery that folic acid produces a prompt haemopoietic response in nutritional anaemia and that 5-methyl-tetrazol (thymine) when given in several thousand times the dose produces a similar response. For the purposes of this study, 32 persons with nutritional macrocytic anaemia, all Europeans aged 35-70, the majority being males, were selected. In this arbitrary selection the following criteria were employed: the red cells were fewer than 3,000,000 per cmm. the bone marrow showed the typical erythroblastic arrest, repeated gastric analyses showed free hydrochloric acid in the gastric content while the intrinsic index was normal and no recent treatment had been given.

Rigid dietetic control in hospital consisted of the exclusion of meat, meat products, poultry and fish, while detailed histories showed that the diets of these patients had been grossly deficient in protein and the vitamin B complex for many years. All patients had lost weight and complained of tiredness and in all diarrhoea had been present from one to three months.

Pain, burning and sensitivity of mouth and tongue were common and many had paraesthesiae and hypoaesthesia. Oedema, associated with a reduction of serum-albumin was present in 9, pellagra, scurvy, riboflavin deficiency and aneurin and ascorbic acid deficiencies in others.

After folic acid treatment, reticulocytosis, increase in haemoglobin and in erythrocytes indicated a satisfactory response in every case. Follow-up studies for eighteen months have shown that none had a severe relapse. The response was adequate to 10 mgm of folic acid daily, which was continued in some patients for as long as 77 days. In contrast to patients with Addisonian pernicious anaemia, no evidence of development of subacute combined degeneration of the cord was obtained. The blood-levels were maintained for eighteen to twenty-four months with no other specific therapy.

COWAN, G. A. B. Folic Acid in Severe Nutritional Anaemia: a Report of Five Cases. *Trans Roy Soc Trop Med & Hyg* 1948, Jan, v 41, No 4, 525-35, 5 figs.

Severe anaemia in Malaya is responsible for much ill-health and many deaths. The causes are malaria, helminthic infection, malnutrition and chronic infections. Out of 142 cases, 24 were found to have red-cell counts of less than one million per cmm. Analysis of these showed that nutritional macrocytic anaemia accounted for nine (three associated with pregnancy), dimorphic anaemia for fourteen and iron-deficient anaemia for one only.

A nutritional factor, apart from iron, was thus concerned in 23 cases, and five of these were treated with oral synthetic folic acid. The total folic acid given was from 160 to 560 mgm in from 16 to 42 doses. Reticulocytes reached their peak on about the 7th day of treatment. In each case the response to treatment was satisfactory; in two it was dramatic, both of these were examples of dimorphic anaemia.

VENOMS AND ANTIVENENES

SERGEANT, Et. Sérothérapie antiscorpionique (dixième note). Observations médicales reçues pendant l'année 1946. [Anti-Scorpionic Sérothérapie X Medical Reports received in 1946] *Arch Inst Pasteur d'Algérie* 1947, June, v 25, No 2, 94-7.

During the year, 868 patients were treated, according to instructions, for scorpion sting: all survived except 4 of the group (124 in number) whose symptoms were alarming and in whom life was endangered. In addition there were 3 deaths in infants who were not treated, and 12 in persons treated with insufficient serum, or too late. The total figures since 1936 are 3,089 treated, of whom 655 showed grave symptoms, of these 655 patients, 592 (90.3 per cent) were cured.

The author points out that patients should be kept under observation for several hours after administration of the serum, even if the symptoms have disappeared, because occasionally the improvement is apparent only, and there

may be a return of symptoms, and death. Instructions are given that if symptoms are severe at least 20 cc. of serum should be injected, and repeated if there is no improvement in one hour and again, several times, if necessary. A return of symptoms indicates another injection.

The scorpions were identified in 39 cases—

- 25 *Pseudoscorpion*
- 11 *P. scorpion*
- 1 *P. pseudoscorpion*
- 4 *Buthus scorpion*

[See also this Bulletin, 1947 v 44 534-535.]

SERENET ET AL. Intervalle de temps qui peut s'écouler entre l'injection de serum antiscorpionique et la sédation des symptômes d'envenimement. [The Time between Injection of Anti-Scorpionic Serum and Alleviation of Symptoms.] *Arch. Inst. Pasteur d'Algérie* 1947 June v 25 No. 2, 98-100, 1 graph.

A study of the symptoms of scorpion sting in 209 cases in which the patients condition was serious before injection of serum shows that alleviation of the local pain, vomiting and sweating occurred within one hour of the injection of serum in 45 per cent. In almost all cases the improvement was evident within 8 hours, though in a very few it was delayed even as long as 18 hours after the injection.

DERMATOLOGY AND FUNGUS DISEASES

VANBREUGHEM R. Importance des affections dermatologiques chez les Européens au Congo Belge. [The Importance of Skin Diseases in Europeans in the Belgian Congo.] *Ann. Soc. Belge de Méd.* T. p 1947 June 30 v 77 No. 2, 251-5

The author reviews the cases of skin affections found among a small European population of about 208 persons, residing in a fairly humid region of the lower Congo from December 1944 to December 1945.

By means of a graph showing monthly rainfall and the percentage of skin cases among his total consultations he demonstrated that skin diseases account for about 20 per cent. of the morbidity rate and are most prevalent in the rainy months.

Mycotic and pyogenic affections comprise about 25 per cent. of the total.

C. C. Chastelain

HADLEY, W. A. Classificação do pénfigo foliaceo baseada em dados anatómicos, clínicos e hematológicos. Classification of Cases of Pemphigus foliaceus. *Tratado de Dermat. e 5 foliografia de São Paulo* 1947 Mar-June 11 Vol. 1/2, 29-56, 1 fig. & 1 graph 1 refs. English summary

Several classifications of this disease have been proposed—that of VIEIRA according to the course—hyperacute, acute, subacute and chronic; but the last is subdivided on a pathological basis into bullous, pustular, papulomatous, pigmented, herpetiform; that of RABELO into 3 clinical types—erythematous, exudative, herpetiform, and exfoliative bullous; that of OSMUND into benign

Dermatology and Fungus Diseases

(*formes frustes*), with scattered lesions, or circumscribed (the Senear-Usher syndrome), and the severe generalized type, subdivided into herpetiform, exfoliating bullous and exfoliating pustular, lastly, that of TORRES into the bullous, the chronic or foliaceous, and the cachectic [see this *Bulletin*, 1945, v 42, 311]

The author proposes a new classification based on the results of blood examination, the clinical course and the histopathology of the skin lesions—a mingling of those cited above. The blood differences are given in a protocol of the averages of 16 *formes frustes* and 314 generalized cases. These differences are not great, the main being a higher eosinophil count of 10,469 and 9,282 respectively, and a differing "nuclear deviation" [? Arneth index], 1/22.5 in the *formes frustes*, 1/14.6 in the generalized type. The histology of the skin in the acute bullous phase, the chronic, the cachectic and retrogressive phases are well shown in a series of photomicrographs, and photographs of patients depict the clinical variations. The chronic phase, the author states, may be further subdivided into foliaceous, erythrodermic and pigmentary forms.

H Harold Scott

FONZARI, M. Doses de metoquina no tratamento do pênfigo foliaceo [The Dosage of Metoquine (Atebrin) in the Treatment of Pemphigus foliaceus] *Arquivos de Dermat e Sifilografia de São Paulo* 1947, Mar-June, v 11, Nos 1/2, 17-28. English summary

There has been considerable conflict of opinion as to the dosage of atebtrin and the length of time for which it can be given with safety, and what intervals should be interspersed when courses of it are administered.

The author has tried it in a large number of cases of *pemphigus foliaceus*. He started with 0.2 gm daily for a week, then, after the lapse of 4 days, repeated the course. Observing no ill effects, he tentatively increased the dose first to 0.3 gm, then to 0.4 and so on, even up to 1.0 gm and maintained it for several weeks, even months, and rarely did he observe untoward symptoms. One man, having had 0.2 gm daily, then 0.3 and finally 0.4 gm till he had had in all 29.4 gm did develop a "toxic psychosis" [not described]. Brief notes—a couple of lines or so to each—are given of 50-60 cases, several were given 80-90 gm in 7 months and one had 110.8 gm in 9 months. Some patients cleared up on this treatment, but commonly a few lesions remained, especially on the legs, and after cessation of treatment these might retrogress. It would appear that when the condition had so far improved as to leave only these few lesions, further treatment with atebtrin was ineffectual. The best results were observed in those who exhibited marked yellowing of the skin, this staining is not to be regarded as a toxic symptom and it clears up in time, whether treatment is continued or not. Other drugs such as paludrine and plasmoquine were tried but were quite ineffectual in this disease.

H Harold Scott

BASSET A. COLDEFY & DE KOUROCH. Trois cas parisiens de pied de Madura dus à une mycose (famille des *Aspergillacées*) [Three Cases of Madura Foot in Paris due to an Organism of the *Aspergillaceae* Family] *Bull Acad Nat Méd* 1948 v 132 Nos 1/2 41-4

DOSTROVSKY, A. & SAGHER, F. Failure of Sulphonamides and Penicillin in Maduromycosis. *Lancet* 1948 Jan 31, 177-8, 2 figs [15 refs]

The authors note that little attention has been paid to the effect of sulphonamides or penicillin on deep mycoses of the skin such references as are quoted refer largely to actinomycotic lesions, and such a one, in a case of Madura

foot, is referred to by PETERS [this *Bulletin*, 1946 v 43 46]. In Peters's case, 1,050 000 units of penicillin were given without specific effect.

The case described by the present authors was one of maduromycosis in a native of Aden. Colonies of a madurella type were found on culture and these resembled *Madurella* *La americana*. Intracutaneous tests with trichophyton and with material from cultures of the lesion were negative. Therapy which included sulphapyridine (total dosage 72 gm.) brought about improvement, but not healing. Three and a half years later the patient was seen again, and there was now considerable involvement of the bones of the foot. Therapy included sulphadiazine (total dosage 100 gm.) and X rays. As this was without effect, sodium penicillin was given in intramuscular doses of 10,000 to 15 000 units every 3 or 4 hours to a daily total of 90,000 units in addition, injections of 10 000 units were given locally into the tumour. In 50 days a total of 5,000,000 units of penicillin was given. Secondary infection was overcome but the mycetoma did not respond and the foot was therefore amputated.

Practical difficulties made it impossible to test the sensitivity of the fungus to penicillin *in vitro*. The authors believe that the failure of penicillin may be explained by (1) insensitivity of the fungus (?) insufficient dosage (3) inadequate contact between the penicillin and the fungus, because of the depth in the bone to which the mycetoma had penetrated.

H J O'D Burke-Gaffney

FRUSS & DELVORE. A propos d'un aspect chirurgical d'une mycose rare histoplasmosse. [Concerning a Surgical Aspect of a Rare Mycosis; Histoplasmosis.] *Cahiers Méd. Union Française Algérie*. 1947 June v. No. 11 419-25 8 figs.

The authors describe a fatal case of histoplasmosis, of an unusual pathological type in a native of Senegal, in which the lesions occurred chiefly in the osseous and cutaneous systems. The upper cervical vertebrae were extensively damaged and a resulting cold abscess, pointing in the posterior triangle of the neck, prompted the diagnosis of Pott's caries of the cervical spine. "Gummatous lesions, in which the large parasitic form of *Histoplasma capsulatum* measuring up to 1.5 μ in diameter was found, occurred in the frontal and maxillary bones, the femur the tibia and the bones of the forearm. *H. capsulatum* was cultivated from the lesions before and after death. The skin over the greater part of the body was thickened dry and cracked in places, and milium ulcers were scattered on the face and limbs. Histological examination of the skin revealed hyperacanthosis of the epidermis with giant-cell granulomata, rich in *Histoplasma* in the cutis. Outstanding pathological features of this case were the unusual distribution of the lesions with apparently no involvement of the lymph nodes or the lungs and only minor involvement of the liver and spleen.

[This is only the fifth reported case of histoplasmosis from tropical and northern Africa. The other four were two diagnosed by the reviewer in 1943 and 1946 one by CATANEI & HERMAN in 1945 this *Bulletin* 1946 v 43 7] and one by HERMAN & VRETAS in 1947 and 1948 v 45 207]. In all, the parasite was of an unusually large size measuring from 12 to 15 μ in longer diameter which suggests that there is a distinct African variety of *Histoplasma capsulatum*.

MILLER, H. E. KEDDIE, FRANCES M. JOHNSON & H. G. & BOSTICK, W. L. Histoplasmosis: Cutaneous and Mucocutaneous Lesions, Mycologic and Pathologic Observations. *Arch. Dermat. & Syph.* 1947 Dec., v 56 No. 6 715-37 3 figs. (Refs in footnotes)

This is a general account of histoplasmosis compiled from the recent literature in which emphasis is specially placed on the mucosal and cutaneous lesions

which are of interest to dermatologists The authors also describe, at great length, the clinical and pathological features of a case of this disease in which the only ascertained lesion of histoplasmosis was an ulcerating nodule, 1.5 cm in diameter, on the dorsal aspect of the tongue The diagnosis was based on the identification of *Histoplasma capsulatum* in scrapings from the ulcer and on the isolation of the fungus from this material There was general lymphadenopathy and some enlargement of the liver, but not of the spleen, A few bodies which may have been *Histoplasma* were seen in some of the cervical lymph nodes, but, on the whole, the microscopical examination of the lymph nodes yielded data more suggestive of Hodgkin's disease than of histoplasmosis The final diagnosis, based on the necropsy findings was generalized miliary tuberculosis, Hodgkin's disease of the malignant lymphoma type and localized histoplasmosis

[It is noteworthy that cases have been described of histoplasmosis and of torulosis which bore a strong resemblance to Hodgkin's disease, not only in their clinical features but in the histology of the lymph nodes, and there is still uncertainty as to whether these were cases of true Hodgkin's disease with superadded mycosis, or the uncomplicated mycoses simulating Hodgkin's disease]

J T Duncan

ROSENTHAL, S R & ROUTIEN, J B **Contagiousness of Coccidioidomycosis**
An Experimental Study *Arch Intern Med* 1947, Sept, v 80, No 3,
343-57, 5 figs [Refs in footnotes]

Infection in coccidioidomycosis is caused by inhalation of the air-borne spores of the saprophytic growth of *Coccidioides immitis*, and the disease is not known to be transmitted directly from man to man The work recorded in the present paper was designed to explore the possibility of direct transmission of the infection by transference of the parasitic spherules of the fungus Experimental infection of guinea-pigs was accomplished by intratracheal insufflation of sputum, pus, ground-up granulation tissue or lymph node material, containing the parasitic spherules, from human sources The infective material was introduced through a wide-bore syringe needle inserted into a tracheotomy opening, and it was driven into the bronchial tree by air pumped from the syringe The resulting lesions of coccidioidomycosis were found chiefly in the upper lobes of the lungs Infection was also effected by intraperitoneal injection of similar materials As a test of survival of the parasitic form of the fungus outside the body, morbid materials containing the spherules were stored for varying periods at 12°C These materials were found to be infective to the guinea-pig by intratracheal insufflation up to 110 days

From the results of their experiments, the authors conclude that coccidioidomycosis should be considered to be contagious until the contrary is proved

J T Duncan

McLAUGHLIN, F W **Coccidioidal Infection** *Bull U S Army Med Dept*
1948, Feb, v 8, No 2, 124-7

Coccidioidomycosis is endemic in the Camp Roberts area in California and since the inception of the U S Army Hospital there in 1941, over 750 cases of *C immitis* infection have been confirmed [this *Bulletin*, 1946, v 43, 778]

The present author reviews 20 of these cases and notes that the usual symptoms were chest pain (20), fever (18) and cough (15) The commonest signs were X-ray evidence of pulmonary infiltration (20), increased sedimentation rate (12) and leucocytosis (8) Hilar adenopathy and pleural effusion were each seen once

It is noteworthy that only 4 of the cases had positive skin tests and the author stresses the point that these tests are negative in many active cases of

coccidioidomycosis. Skin tests may however become positive very rapidly and a detailed account is given of one patient on whom such a test was positive at 1/1,000 on the fifth day after mild symptoms were noticed. On the other hand, complement fixation and precipitin tests do not always become positive early—a case is quoted of a patient having X-ray evidence of a chest lesion and showing a positive skin test at 1/1,000 but whose complement fixation did not appear for over 3 weeks.

The two serological tests are usually necessary for final diagnosis, since lesions seen in chest films so closely resembled those of tuberculosis. In many cases skin tests for tuberculosis and for coccidioidomycosis were both positive and indeed occasionally the two diseases may co-exist.

The best method of diagnosis is probably obtained by culture of sputum and guinea-pig inoculation, where facilities are available. The author found the raised sedimentation level to be fairly frequent [the figure of 60 per cent. is given but the numbers were only 17 out of 20]. He also believes the sedimentation rate to be of prognostic significance especially since its return to normal tends to correspond with X-ray evidence of clearing. It is suggested that the sedimentation level is an important factor in determining when a patient may become ambulatory (as in the case of rheumatic fever).

No specific therapy was found and penicillin and sulphonamides proved ineffective. Treatment was largely a matter of general principles and good nursing.

H J O'D Burke-Gaffney

MISCELLANEOUS DISEASES

RAYMOND W D Notes on a Poisonous East African Species of WED
Cucumber (*Cucumis aculeatus*) East African Med J 1947 Dec., v
No. 12, 450-51

The toxicity of a number of species of wild cucumber has been investigated in South Africa—it has been shown that *Cucumis africanus* and other species contain a toxic principle cucumin, which is neither a glycoside nor an alkaloid. In human poisoning violent diarrhoea has been noted. In laboratory animals, postmortem appearances varied with the dose—with small doses, the gastrointestinal tract was principally affected—with large doses, pulmonary oedema was the usual cause of death.

The author describes a fatal case of poisoning of an African in Tanganyika who was treated for headache by a local medicine man with the fruit of a plant *Amisane*—this was identified as *Cucumis aculeatus*. Vomiting and diarrhoea occurred soon after the medicine was taken. Death took place within 8 hours and although the passage of time during transport obscured the autopsy findings, pleural adhesions were noted.

From the fruits a substance was isolated which gave reactions similar to those described for cucumin—it is highly probable that the fruit contains a substance closely related to if not identical with, cucumin.

The substance isolated and fresh extracts of the fruit were lethal, within 1 to 8 hours to a mouse, two white rat and frog, on injection. In the rats and the mouse dyspnoea and cyanosis were noted and the pathological findings in the lungs at postmortem showed that they had the appearance one would find in acute pulmonary oedema.

Other local species of *Cucumis* known to be poisonous are *C. ficusoides*, *C. ficiformis* and *C. hirsutus*. Poisoning has also occurred from other species not exactly identified botanically.

H J O'D Burke-Gaffney

- DONOSO BARROS, R Myiasis humana en Chile Consideraciones clinicas y epidemiologicas [Human Myiasis in Chile Clinical and Epidemiological Features] *Rev Chilena de Hig y Med Preventiva* 1947, Mar, v 9, No 1, 3-59, 3 figs & 10 pls [83 refs]

The author bases his remarks on 112 cases of human myiasis under his personal observation during the five years ending 1946. The numbers in successive years were 1, 2, 7, 17 and 85. 7 were under 5 years of age, 10 each between 36 and 40, and 46 and 50 years. His own observations are supplemented by references to and quotations from the literature and there is a very full bibliography. The author divides his cases into two main groups. Myiasis of cavities (*i.e.*, orifices), nasal, aural, ocular, vulvovaginal and intestinal (including the mouth). The second group is that of cutaneous myiasis, attacking the unbroken skin or lesions such as ulcers, wounds, etc. The following larvae were identified: *Cochliomyia hominivorax*, *Calliphora erythrocephala*, *Musca domestica*, *Musca chilensis*, *Fannia canicularis*, *Eristalis tenax*, *Oestrus ovis*, *Gastrophilus veterinus*, *Sarcophaga carnaria* and *Parasarcophaga barbata* [*Sarcophaga barbata*]. In previous accounts *C. macellaria* has been named as causing myiasis in Chile, but this, it is stated, was a mistake for *C. hominivorax* [though some authors use the names as synonyms]. - MILLER, J M & THOMISON, S J Surgical Aspect of Infestation with Intestinal Parasites *Southern Med J* 1948, Feb, v 41, No 2, 178-80

"Case reports of patients with *Enterobius vermicularis*, *Schistosoma japonicum*, hookworm, and amebiasis have been presented. The discovery of parasites in patients with otherwise unexplained abdominal symptoms will remove this group of individuals from those with the unsatisfactory diagnosis, 'abdominal pain, cause undetermined'. The surgeon is urged to familiarize himself at least superficially with these parasites, that he may consider them in his differential diagnosis of unusual abdominal pain."

PROTOZOOLOGY GENERAL

- APPELBAUM, A Human Toxoplasmosis Report of a Case in an Adult with Ocular Manifestations *Ann Western Med & Surgery* 1947, Oct, v 1, No 8, 323-32 [27 refs]

The paper describes a case of toxoplasmosis in a white man 30 years of age and gives a general summary of the literature of the subject. The case in question was examined because of the patient's complaint of blurred vision of the left eye, a small patch of chorio-retinal atrophy was found just temporal to the fovea centralis, together with a small recent haemorrhage between the patch and the fovea centralis. Two years later the patient was again examined and he now revealed a bilateral central chorio-retinitis. The lesion in the left eye had increased in size and showed a black pigmented centre and a zone of peripheral pigment. In addition, two other small lesions had appeared. As toxoplasmosis was suspected, a serological test for neutralizing antibodies was carried out. This was positive. Cerebrospinal fluid injected into mice did not give rise to infection. The author points out that this case is the forty-second to be reported in the U S A since 1939. Of these cases, nine occurred in persons over 15 years of age.

C M Wenyon

KRAY, B. H. & GRACOTT, R. G. Asymptomatic Toxoplasmosis. *Am J Trop Med.* 1947 Nov. v 27 No. 6 45-8, 1 fig. (17 refs.)

A man 29 years of age died from an accident, and examination of sections of the heart muscles revealed a cyst measuring 34 by 98 μ . It was filled with spores, 250 being countable in the section. There was no inflammatory reaction round the cyst. Extensive examination of further sections from the heart and other organs failed to reveal any other parasites. It is thought that the cyst shown in a microphotograph represents a toxoplasma. C. M. Warren

ENTOMOLOGY AND INSECTICIDES GENERAL

LIMSDEN, W. H. R. Observations on the Effect of Microclimate on biting by *Aedes aegypti* (L.) (Dipt., culicid.) *J Exper Biol.* 1947 Dec. v 4 Nos. 3 & 4 361-73 2 figs. (23 refs.)

The mosquitoes were reared under carefully controlled conditions, and were offered a blood meal in a small cage applied to the human arm in darkness. It was found that wide variations of the relative humidity did not appreciably affect the proportion biting, which rose from about 10-20 per cent. at 10 C. to a maximum of 90 per cent. (within five minutes) at 35 C. Only about 60-70 per cent. fed at 40 C. Measurements of temperature gradients near the human skin were made with a sensitive electrical thermometer. At air temperatures below that of the skin, the gradient extended away for only about 1 cm. in nearly still air. At air temperatures above the skin there was a gentle reversed gradient for 2-3 cm. It seems unlikely that these gradients can be responsible for attracting mosquitoes to bite, especially when the air temperature is above that of the skin.

Dissections showed that in the majority of fed mosquitoes, blood was found in the stomach alone, but in partly fed mosquitoes there was a somewhat larger minority with blood in the diverticula also, probably because of regurgitation when feeding was interrupted. J. R. Hunter

SWALLENGREBEL, N. H., LODEN, J. G. & SWALLENGREBEL, J. M. H. Rapport over proeven met de bereiding van insecticide-mengsels met DDT in Tjandjoer en omgeving. [Trial of DDT "Foliar Spraying" at Indonesian Dwellings.] *Med. Maandblad. Batavia* 1947 Dec. v 17 319-23

SCHMITZ, W. R. & GOETTLE, Mary B. Penetration of DDT into Wood Surfaces. *Soap* New York 1948, Jan. v 24 No. 1 118-21 2 figs.

Two types of DDT spray were used: kerosene solutions and aqueous emulsions of DDT dissolved in various solvents. The liquids were carefully sprayed on to strips of wood with an atomizer and the penetration was subsequently judged by extraction and chemical (colorimetric) estimation of DDT from layers scraped off the surface. The thicknesses of the layers of peeling were estimated by a craze micrometer measurements.

The authors used a variety of woods and the average recovery of DDT (kerosene solutions) from the first 0.001 inch was 5 per cent., and from the

first 0.006 inch 52 per cent, of the amount theoretically applied. Equivalent figures for emulsions, were 37 and 70 per cent respectively. At depths below 0.006 inch the amounts in different layers fell away asymptotically (Thus, at 0.04 inch the quantities recovered were still only 65-85 per cent.)

There was little evidence of correlation between the physical properties of the different woods and the recovery of DDT from the upper layers. Preliminary spraying of wood with water did not greatly improve DDT recovery if the DDT liquid was sprayed on immediately afterwards, but there was definite improvement after one spraying with water and drying for fifteen minutes before application of the DDT.

Tests with different solvents in the emulsion formula suggested that the more volatile DDT solvents tended to leave more DDT near the surface.

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

BULL. MÉD. DE L'AFRIQUE OCCIDENTALE FRANÇAISE 1946, v. 3, No. 2, 271-84. L'actualité médicale dans l'Ouest Africain. Conférence médicale Franco-Britannique d'Accra—Novembre 1946 [Franco-British Medical Conference, Accra, 1946].

The agreements reached at this Conference are set out *seriatim*. They cover — A. Cooperation between health services in the various countries of West Africa, and proposals for coordination of medical action, B. Agreements relating to the medical instruction of Africans, C. Facilities for the diagnosis of yellow fever (the accredited laboratories are at Dakar, Freetown, Accra, Lagos, Douala, Stanleyville, Brazzaville), D. Preparation and distribution of vaccines for mutual assistance, E. Collaboration in studies of nutrition, F. General principles of closer cooperation between the various countries, G. Final recommendations, in which it is noted that Belgian and other representatives agreed to the principal resolutions.

There are three Annexures, dealing respectively with mobile medical organizations, schedules of instruction for Africans, and the organizations interested in nutrition.

No adequate summary of this Conference can be given, the resolutions are given with little comment, and should be studied in the original. There is evidence of a desire to improve inter-territorial medical collaboration.

Charles Wilcocks

MALAYA. **Annual Report of the Institute for Medical Research, Malaya, for the Year 1946** [LEWTHWAITE R., Director] 52 pp 1947. Kuala Lumpur. Malayan Union Govt. Press. [\$1 or 2s 4d.]

In the introductory part of this Report, Lewthwaite briefly traces the history of the Institute since its foundation in 1900. He gives an account of the action taken just before the Japanese occupation, and in more detail, after the capitulation of the Japanese in 1945. The loss of equipment during the occupation was almost complete, and the laboratories were re-equipped from whatever sources could be tapped.

The demand for vaccines after the war was very great and was met with difficulty supplies were also needed for Siam and Borneo.

The author pays tribute to his colleagues not only for their scientific work in peace but also for their service in war several lost their lives and many of them suffered severely.

Work is now continuing as routine investigation or special research, in the Divisions of Bacteriology, Chemistry, Entomology, Malaria Research, Nutrition, Pathology and Serology and the branch laboratory at Ipoh is once more functioning. Records of these activities are displayed in the report.

Charles W. Weeks

NEW ZEALAND WESTERN SAMOA. Twenty-Fourth Report of the Administration of the Territory of Western Samoa for Year ended 31st March, 1947 [VOELCKER, F. W.] 27 pp. Wellington Govt. Printer

Western Samoa comprises two large and several small, mountainous, islands. The climate is mild and equable the mean daily maximum temperature being 84.75°F minimum 73.82°F and the average annual rainfall 111 inches. The population consists of 5,763 non-Samoans and 65,685 Samoans most of the latter live in coastal villages. The islands are administered by the Government of New Zealand under the international trusteeship system of the United Nations, but their status is under review.

The medical section of this Report (p. 19-23) is brief. The staff consists of 3 European medical officers, 22 Native medical practitioners, 7 Native dental officers, 1 qualified bacteriologist of part-Samoan descent, 11 European nursing sisters, 97 Native nurses, and others. There is a considerable hospital at Apia, which accommodates Europeans, Samoans and Chinese and includes a laboratory and X-ray department. There are 13 medical out-stations to each of which a Native medical practitioner and nurse are attached. At all stations, in 1946 there were 3,631 in-patients and 99,104 out-patients.

The principal infective diseases reported in 1946 were tuberculosis (43 cases), malignant jaundice [not otherwise defined] (71), catarrhal jaundice (9), pneumonia (244), bronchopneumonia (73) and enteric fever (37). The tuberculosis situation was investigated by Dr C. A. TAYLOR (New Zealand) who concluded that it was not particularly serious.

The infant mortality rate was 106 per 1,000 registered births in 1926, 291.77 in 1936 (the high figure was the result of epidemics of whooping cough and measles) and 64.05 in 1946.

SUMMARY OF RECENT ABSTRACTS*

V LEISHMANIASIS

VISCERAL LEISHMANIASIS

Epidemiology. Aetiology. Transmission

FALCÓN TREJO (p 984) reports kala azar from Badajoz, Spain

An account of leishmaniasis in Greece is given by MALAMOS (p 1), who considers the geographical distribution of kala azar (here a disease of infants), canine leishmaniasis (due to *L. donovani*), and oriental sore. The chief vector of kala azar in Greece is *Phlebotomus major*, and of oriental sore *P. sergenti*, only occasionally is *P. papatasi* involved.

HO *et al* (p 987) have found visceral leishmaniasis in dogs in part of China where kala azar is present. Leishmania were found in the skin of most of the infected dogs.

SHIH LU CHANG (p 1055) describes two media, one semi-solid, the other fluid with a solid base, for cultivation of leishmania and *T. cruzi*. Both give better growth than the media usually employed. For details the original should be consulted. With the solid-base medium, SHIH LU CHANG and NEGHERBON (p 1056) have studied the growth characteristics of various species of leishmania, and of *T. cruzi*, but for details the original should be consulted.

PEREIRA and MEDINA (p 188) describe a method of staining leishmania, especially in tissues.

ADLER (p 983) has observed the behaviour of a Sudan strain of *L. donovani* in *P. papatasi*, the infection rate was low in sandflies fed on a diseased hamster. The infection rate provides one means of differentiating strains of *L. donovani*. Differentiation of the various species of *Leishmania* may be determined by consideration of results of cultivation experiments, infection of hamsters and of sandflies. For details the original should be consulted.

DE AZEVEDO and TELHEIRA (p 981) note the various species of *Phlebotomus* found in Lisbon in summer and autumn, and their habitats and blood preferences. Only 2 per cent showed positive precipitin tests with anti-human sera, whereas 22.5 per cent were positive with anti-bovine serum.

DOLMATOVA (p 982) has studied the sandflies of a district in the Caucasus. In this area there are numerous burrows, some occupied by birds, and the

*The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947 v 44. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

sandflies breed in these burrows. Several species known elsewhere to transmit kala azar occur here—the author thinks that *P. perniciosus* var. *hads*, is probably a natural vector of *L. donovani* as it can be infected experimentally and attacks man.

SHORTT (p. 511) has answered the criticisms previously made by Malone and Brooks [this Bulletin 1944, v. 42, 357] on the experimental work done on the transmission of kala azar by *Phlebotomus argentipes*. FENG and CHENG (p. 1055) report (for the first time) successful transmission of kala azar from dog to hamsters by the bite of *P. chinensis*, and also that hamsters became infected when inoculated with flagellates from *P. argentipes* var. *mongolensis* previously fed on an infected dog.

Diagnosis Clinical Findings

DR AZEVEDO (p. 834) writing from Portugal, notes that the various standard methods of diagnosis of kala azar may give negative results, and advocates examination of material from the nose for leishmanias. With a platinum loop the mucous membrane is scraped until the surface is broken—in 11 cases examined, 9 were positive. The procedure is simple but it is necessary to break the surface since the organisms are in the histiocytes of the submucosa.

The cephalin-cholesterol flocculation test was found by MAKARI (p. 238) to be strongly positive in eight cases of infantile kala azar.

DIARMENDRA *et al.* (p. 189) have prepared an antigen from Hedrowsky's acid fast bacillus to be used in a complement fixation test for kala azar.

ADLER (p. 983) shows that in leishmanias there is proliferation of the reticulo-endothelial cells and also a secondary round-cell infiltration—he thinks that the latter reaction is a curative one, and that lymphocytes play some part in defence. This reaction is marked in dogs (in which the disease is usually chronic) but is slight in spermophila (in which the disease is acute and fatal).

PARRINELLO (p. 297) reports on the condition of the blood in infantile kala azar in Italy.

FELDMAN (p. 297) describes kala azar in a British soldier who had served in the Mediterranean—the disease developed 4 months after return to England. NORMAN (p. 54) mentions a case of long latent period in kala azar.

DEMOMO (p. 865) states that in Malta, kala azar is a disease of young children rather than of infants. He describes the incubation period, onset and course of the disease and the means he uses for diagnosis and treatment. It responds well to intra-venous antimony.

Treatment

VAN DYKE and GILLMORE (p. 512) have tested in hamsters 168 new compounds for activity against the Sudan strain of *L. donovani* but none has proved better than the recognized drug.

The same authors (p. 286) noting that pentavalent antimony compounds are more effective and less toxic than trivalent compounds in leishmanias, describe investigations to find if there is a correlation between therapeutic activity of a drug and the amount of antimony present in liver and spleen of treated animals. The results were essentially negative in that the presence of high concentrations of the drugs (pentavalent compounds) was not synonymous with cure.

KIRK (p. 984) reviews the treatment of kala azar in the Sudan where the use of antimony cures in 70 per cent of cases which would almost all be fatal without it. Use of the diamidines has further improved the results of treatment. The appearance of dermal lesions during or after treatment is of good prognostic significance—they may persist 20 years or more without affecting health.

KIRK and SATI (p 885) in the Sudan report favourably on the results achieved in kala azar with sodium antimony gluconate [sodium stibogluconate] given intravenously in concentrated solution, for 6-10 injections, over a short period (as short as 6 days in some cases). The results in a small series were better than when the drug was given in smaller doses over a longer period, and the brevity of the course is in itself an advantage. MAEGRAITH *et al* (p 886) treated eight patients with kala azar (Indian or Mediterranean strains) with sodium stibogluconate, with one death and seven cures. The drug was given intravenously, once or twice daily for 10 days, and severe reactions occurred in five patients, and were attributed to it. In the fatal case there was shock and circulatory failure after the last dose, but the actual cause of this could not be ascertained at post mortem examination. There was no evidence of accumulation or anaphylaxis, nor was it due to a defective batch of the drug. Cure was confirmed parasitologically, sometimes 3-4 months later. CHOUDHURI (p 298) reports cure in 22 of 23 patients with kala azar (in India) treated with sodium antimony gluconate (Stibatin).

SARROUY *et al* (p 55) have used a new antimony preparation (antimoniate of N-methylglucamine) in the treatment of a child with kala azar, it was successful, but the dosage has not yet been determined, though the preparation is said to be only half as toxic as Pentastib. DURAND *et al* (p 56) report further use of this drug, confirming its value and low toxicity. It is rapidly excreted by the kidneys. They treated 6 cases with very good results, though sufficient time has not yet elapsed to decide if permanent cure has been obtained. SARROUY *et al* (p 807) report three more cases successfully treated with this drug, which they regard as the most efficacious yet discovered.

The antimony content of different batches of urea stibamine varies, and the drug is not a compound of uniform formula. BOSE *et al* (p 189) have worked out the toxic dose for mice, but there is considerable variation. Assay of the drug must still be made biologically, since the relation of antimony content to toxicity is not known, and there is no indication which fraction is therapeutically active. To avoid the toxic symptoms which often arise as a result of treatment with urea stibamine, HO (p 189) in China gives relatively small doses for kala azar, and has found that with these, given once or twice each week, most cases are cured.

HARRISON and FULTON (p 190) describe the changes which take place in the spleen of *Cricetus auratus* on infection with *L. donovani*, and show that although the enlarged spleen diminishes in size on treatment with 2-hydroxy stilbamidine, there is always a residual splenomegaly, even after cure. FULTON and DUNITZ (p 988) discuss the constitution of the toxic substance created when stilbamidine is irradiated. SALTZMAN (p 988) describes a method for estimation of stilbamidine in urine and blood, but FULTON, in comment, criticizes the technique employed.

ADLER and TCHERNOMORETZ (p 406) have failed to cure dogs, naturally infected with *L. infantum*, with stilbamidine or neostibosan. There is always a residual skin and gland infection, even after intensive treatment, and the authors therefore advise that as such dogs serve as a reservoir for disease in man they should be removed from endemic centres or destroyed.

CUTANEOUS AND MUCO-CUTANEOUS LEISHMANIASIS

STEINHAEUER (p 987) describes the recurrent form of cutaneous leishmaniasis which is common in Palestine. This form simulates lupus vulgaris, and leishmania are difficult to demonstrate except by cultural methods. The intradermal leishmania vaccine reaction is positive in 97 per cent of cases, and biopsy shows characteristic tuberculoid structure. He reports a case of a

verrucose form of this disease which though common in South America, is rare in the Middle East.

PIERS (p. 869) reports a case of muco-cutaneous leishmaniasis from central Kenya, and notes a few cases of kala azar from the same area. This is the first time that cases have been reported from this place and it is not known whether a focus existed before or whether the disease has been introduced as a result of troop movements from Abyssinia. Penicillin treatment produced some improvement in the muco-cutaneous lesions.

AXSAKI (p. 191) uses penicillin to control bacterial infection when isolating *L. tropica* in culture. He adds 1,250 units to each cubic centimetre of N.A.N. medium.

AXSAKI (p. 887) describes a substance in commercial preparations of kamin B which stimulates growth of *L. tropica* in culture, and another which inhibits it. The former is heat labile, the latter heat-stable.

JERACE (p. 808) has found *P. perforans* in the Abruzzi area of Italy, where it is the vector of oriental sore.

Working in Calabria, TIMPANO (p. 289) claims to have transmitted oriental sore from man to man, three times by mosquitoes and once by sandflies. The maeets (and houseflies) were allowed to feed on sores, and were then transferred to healthy persons, on whom they fed. He also claims to have found flagellates in the pharynx and stomach of two mosquitoes and a sandfly. In comment, WENYON remarks that the arrangement of the experiments seemed to favour mechanical transmission rather than development of leishmania in the flies, and comments on the shortness of the incubation period (17-15 days).

DOUMATOVA (p. 887) has made observations on the biology of *P. papatasi*, *P. sergenti* and other sandflies in a focus of oriental sore in Tadzhikistan. They have, apparently, no food preferences, but feed on the most accessible animals.

KIRKMAN (p. 190) states that *P. rousselli* is probably the common transmitter of cutaneous leishmaniasis in the French Sudan.

The histo-pathological processes involved in the invasion of the tissues of mice by *L. tropica* have been described by LARIVON and SKABOVSKAYA (p. 888), and details should be sought in the original abstract. The infection was initiated by inoculation of *L. tropica* from the moist type of human oriental sore.

DOSTROVSKY and SAGHER (p. 1058) have found in a number of trials, that the culture method of diagnosis in oriental sore gives more positive results than examination of smears for leishmaniasis, particularly in old, chronic cases, in which the lesions may resemble those of lupus or syphilis. SAGHER (p. 807) has used a vaccine of *L. tropica*, in graded dilutions, for skin tests in cases of oriental sore of various types. He concludes that in the recurrent type (with infection lasting more than one year) there is a more pronounced allergic component than in the nodular form (with infection of less than one year). DOSTROVSKY and SAGHER (p. 887) have found the intracutaneous test (with the vaccine prepared by the former) positive in most cases of oriental sore (either nodular or recurrent) tested in the Jerusalem area, whereas examination of the lesions for parasites was negative in more than half of the cases. The chances of non-specific reactions are small.

ROMAÑA et al. (p. 360) have found a focus of cutaneous leishmaniasis in Tucumán, Argentina.

PESSOA and BARRETO (p. 300) summarize the evidence that American cutaneous leishmaniasis is most common in men whose work takes them into forests where sandflies abound.

Charles H. Wells

RABIES

UNGARI, C Meningoencefalomielite da virus rabico a decorso clinico anomalo
[Meningo-encephalitis due to Rabies Virus, having an Atypical Clinical Course] *Pediatrics* 1943, Feb, v 51, No 2, 52-8

The author refers to the difficulties experienced in deciding, when an acute ascending paralysis of the Landry type occurs at the end of or shortly after completion of anti-rabies treatment, whether it is a latent encephalomyelitis activated during the treatment, a paralytic accident of vaccine treatment or a case of rabies caused by street virus or fixed virus modified by vaccination

A case of street virus infection which followed an atypical course is described

A girl aged 7 years was bitten on the face by a stray dog, later confirmed by biological tests as having been rabid. Local disinfection was effected and anti-tetanus serum given within a few minutes, intensive anti-rabies treatment was commenced with PUNTONI's phenolized vaccine within 48 hours. On the 21st day of treatment (23 days from the date of bite), the child suddenly developed high fever, followed two days later by signs of a paralysis which ascended from the lower limbs to the cranial nerves before death supervened on the 9th day of illness.

The main symptoms were those of paralysis with fairly well marked meningeal signs, itching in the bite scar and changes in the mental state (agitation, hallucinations, delirium). At no time was there hydrophobia or aerophobia, deglutition remaining comparatively unimpaired until death.

Histological examination of the brain revealed no Negri bodies, but the so-called Babes nodules were found in the superior olivary body.

Biological tests made on two guinea-pigs by the inoculation of bulbar material resulted in the death of the animals on the 18th day, with the presence of numerous and typical Negri bodies in the horn of Ammon. A second and third passage resulted in death of the test guinea-pigs on the 11th and on the 7th days respectively, with similar post mortem recovery of Negri bodies. The diagnosis of street virus was therefore established.

The difficulties of establishing a differential diagnosis on clinical grounds alone are discussed

G Stuart

CAMPBELL, T C & DEFRIES, R D Some Observations on the Preparation of Rabies Vaccine using Phenol [Abstract.] *Canadian J Pub Health* 1948, Feb, v 39 No 2, 82

The introduction of the mouse test by Webster in 1939 made possible the determination of the antigenicity of rabies vaccines. As a result vaccines of greater antigenic value have been prepared. A modification of the method of preparing rabies vaccine employing phenol (Semple method) is described in which phenol, 1 per cent, is added to a 30 per cent suspension of rabid brain tissue in place of an 8 per cent suspension as usually employed in the preparation of rabies vaccine by the Semple method. The antigenic value of the vaccines so prepared has exceeded the minimum standard as recently established by the National Institute of Health, Washington, namely protection against 1 CCU MLD of challenge virus. A change, also, in the strain of virus in the preparation of both human and veterinary vaccines may be a contributing factor to their improved antigenicity. Vaccines for veterinary use prepared from rabid calf brain tissue possess a much greater antigenic value than vaccines made from rabbit brain tissue. Observations over a period of years of veterinary vaccines prepared from calf brain and processed by this method indicate that their potency is retained for a much longer period than that of

vaccines prepared by the standard Semple method for human use. The destructive action of freezing on rabies vaccines containing phenol is low. Further supporting evidence of this fact is supplied.

HABEL, R. & WRIGHT, J. T. Some Factors Influencing the Mouse Potency Test for Rabies Vaccine. *Pub. Health Rep. Wash.* 1948 Jan. 9 v. 63, No. 7 44-55 3 figs.

A mouse test for the potency titration of rabies vaccine was first described by HABEL in 1940 since when official recognition has ensured its routine adoption as the basis of a minimal potency requirement of all rabies vaccines produced in the U.S.A. for human or veterinary use.

Variations in the results of the test have however been observed by workers in different laboratories and it was in order to determine the factors responsible for such variations and, if possible to eliminate them that the study described in this paper was undertaken.

In this connexion the influence of (a) technician, (b) strain of mice and (c) strain of test virus was closely investigated, with the result that in (b) and in (c) probable explanation was found.

Thus as regards (b) it emerged that with the technique employed in the standard test strains of mice at the age of 4 weeks may vary in their ability to be immunized with a particular rabies virus. As regards (c) it was shown that a wide variation of invasiveness (i.e. the ability to cause rabies in immunized mice) exists among fixed viruses even if as in the present study substrains of the original Paris (Pasteur) fixed virus are used. The substrains in question had been carried in different laboratories over a period of years by different individuals using different intracerebral passage techniques; any differences in their present characteristics must therefore have occurred through repeated animal passages over a long period of time.

In the light of the above findings, the authors consider it necessary to standardize the technique of the test and in this sense detail requirements for an acceptable determination of potency.

Of these requirements reference need only be made here to (a) type of test mouse and (b) the standard test virus.

(a) Type of test mouse.—The test is based on the use of white Swiss mice of either sex approximately four weeks old uniform in weight (11-13 gm.).

(b) The standard test virus.—A standard test virus will be supplied by the National Institute of Health preferably only on request at approximately yearly intervals. The use of such a standard virus will largely eliminate virus variations from routine potency testing. A standard virus may be obtained from pooled frozen virus which, as has been shown will retain its titre for at least 10 months with relatively slight variation in the titration end points from test to test. Further to reduce the possibility of a standard virus changing its characteristics because of animal passage in different laboratories, the number of passages of the reference standard test virus actually used in determinations of potency should be held to a minimum. C. Stuart

AMERICAN J. PUB. HEALTH. 1949, Jan. v. 39, No. 1 Pt. 1 97-9 Recommended Methods for Rabies Control. Adopted by the Committee on Research and Standards, October 6 1947 American Public Health Association.

A Conference on Rabies held in April 1947 (Philadelphia, Pennsylvania) and reached complete agreement on the means whereby rabies control, undertaken on a national basis, could best be effected in the U.S.A.

The following paragraphs summarize the principal recommendations

1 Active cooperation on the part of the Federal Government

(a) by contributing funds and personnel to affected States ,

(b) by establishing a central bureau for the collection from and distribution to States, agencies and individuals concerned in the control programme, all information on the incidence among animal species and on the place of occurrence of rabies

2 Prime consideration should be given to (a) adequate diagnostic facilities, (b) the control of animals capable of transmitting the disease , and (c) mass immunization of susceptible animals, particularly dogs

(a) and (b) need no comment , they conform to orthodox procedure

As regards (c) it is held that the vaccination of dogs, combined with other control measures, provides the most satisfactory method for the prompt control of rabies. Evidence shows that a single 5 ml subcutaneous injection of an accepted canine rabies vaccine is effective in a mass vaccination campaign, but that the administration of three doses of such vaccine in 5 ml amounts, one week apart, affords greater immunization. To secure permanent reduction in the number of susceptible dogs, annual immunization is advocated.

Vaccinated dogs, identifiable as such by suitable tags, may be allowed at large 30 days after vaccination. Finally, the need is emphasized for a comprehensive educational programme to bring the subject of rabies and its control before the public

KORNS, R. F. & ZEISSIG, A. **Dog, Fox, and Cattle Rabies in New York State Evaluation of Vaccination in Dogs** *Amer J Pub Health* 1948, Jan v 38, No 1, Pt 1, 50-65, 11 figs

This article describes an epizootic of rabies continuing since 1943 in New York State and details measures for its control among the animal species affected there

1 *Incidence*—The epizootic has been characterized by the introduction and spread of the virus among foxes and cattle, with a concurrent sharp decline in canine rabies—a decrease ascribed in large measure to the extensive practice of dog vaccination. Thus in 1946, rabies was reported in 377 dogs, 308 foxes and 440 cows, during the first nine months of 1947, it was reported in only 40 dogs, but in 218 foxes and 173 cows. Rabies in cattle seems clearly to have been due to the bites of rabid foxes, fox rabies, with, as corollary, cattle rabies, has spread in a slow radial fashion over a period of two years.

2 *Control Measures*—(a) Control of the dog problem—Following on the acceptance of the HABEL rabies vaccine potency test and on the demonstrated value of approved anti-rabies vaccines in canine prophylaxis, a further measure of control has been added to that previously in force, *viz* restriction of the activity of dogs in areas where rabies was certified by the State Commissioner of Health to be present.

To be effective, mass vaccination of dogs presupposes immunization, spread over an area at least county-wide, of not less than 70 per cent of the enumerated dog population, it should be carried out in as short a period as possible, preferably within a month, so that the majority of the dogs in the area will attain maximum levels of immunity about the same time. When this percentage is achieved, the Commissioner of Health may designate 'certified areas' (*i.e.*, where rabies exists) as areas in which vaccinated dogs may be allowed to run at large—such designation to terminate in 12 months unless the immune status of the dog population is maintained by revaccination. The general practice has been to give each dog only one injection of 5 ml of vaccine, repeated yearly.

Evidence of the value of mass vaccination is adduced from the experience of 10 counties wherein 8 per cent. of the enumerated dogs were immunized. There the rabies attack rate in non-vaccinated dogs was 15.8 times as great as that in vaccinated dogs observed during the same period and in the same area.

(b) General recommendations for rabies control include mass vaccination combined with ordinary measures of dog control. Anti-rabies measures to be initiated as soon as incidence is reported in adjacent counties. The appointment of a full-time veterinary consultant on State level, to promote and supervise the control programme. The contribution of financial aid to counties for dog vaccination clinics. Adequate education of the public concerning rabies.

(c) Control of the fox problem.—This has been attempted by the creation, through trapping, of a zone of fox scarcity surrounding the infected area.

MALARIA

SAUPARKER, J. Malaria in Czechoslovakia after World War II. *J. Parasitology* 1947 Dec. 33 No. 8, 568-8.

Although natural conditions favourable to the propagation of malaria exist in Czechoslovakia malaria was unknown in the western parts of that country since the 1850's until the end of World War II. Then, two events of troops and civil populations and changing epidemiological conditions caused the occurrence of malaria in two territories which are quite apart from each other, namely Southern Moravia and north-western Bohemia.

The anophelines of Czechoslovakia are found in the plains and in the lower hilly country. Rarely are they found in free nature but are mostly met with in warm quiet stables and occasionally in human dwellings. The species found are *A. claviger*, *A. maculipennis maculipennis* and *A. m. messeae*.

The part of Southern Moravia which was affected is flat and richly irrigated agricultural country. Wartime destruction of stables and cattle on a large scale caused the mosquitoes to lose their predominantly zoophilic character and to turn to human hosts. The retreating German armies withdrawing through Moravia were followed by the Russian army which contained Rumanian units from the highly endemic Balkans. Soldiers carrying malaria parasites passed the infection on to mosquitoes and hence to the human population. Furthermore damaged sewage and irrigation systems and bomb craters became breeding places for mosquitoes.

The affected area in north-west Bohemia was infected from a different source. This territory is a lignitic coal-mining district with many shallow shafts. In deserted and sunken mines there are undisturbed pools which breed large numbers of mosquitoes. During the war large synthetic petrol factory was built and labourers including prisoners of war were brought from many countries, such as the Balkans and Italy. With them came numerous persons with untreated malaria.

The author is unable to provide detailed statistics, as the official reports did not distinguish fresh cases of domestic origin from malaria contracted outside Czechoslovakia. He draws, however, on cases reported in the local medical journals and refers to 14 cases in Moravia and in Bohemia in the first year after the war and 31 and 10 respectively in 1946. The increase in 1946 is explained by lack and incomplete cure and it is added that the form of malaria seen in Czechoslovakia shows great tendency to relapse.

Malaria

Vol 45, No 6]

All infections were caused by *P vivax* and infections with two generations, showing a quotidian fever, were common. An outstanding feature of the infection as seen in Czechoslovakia is the severe initial anaemia, characterized by red cell counts as low as 2 million per cmm and haemoglobin often lower than 50 per cent. Such a severe anaemia is not found in the established endemic areas of Europe, and the relatively malignant course of *P vivax* infections in Czechoslovakia is explained by lack of previous infection and a generally lowered resistance. The disease was successfully treated with the usual doses of quinine and mepacrine.

It is remarkable that no great epidemics occurred, in spite of the conditions favourable to them, it is suggested that energetic isolation and treatment helped to localize the disease.

The present importation of further labourers from the Balkans and Italy may cause a fresh wave of malaria, and this possibility must be taken into account by the health authorities for some years to come.

[This is yet another example of the disruptive effects of man-made destruction of biological equilibrium even when such interference is benevolent—as in the case of large-scale, aerial DDT spraying and its effects on wild life, or the mutations brought about by bacterial resistance to newer chemotherapeutic agents—some of the ultimate biological implications are often unpredictable.]

'ETA, T L'infezione malarica a Gondar [Malarial Infection in Gondar]
Riv di Malariaologia 1947, Dec, v 26, No 6, 296-9

The English summary appended to the paper is as follows —

"After stating that an estimate of the malarial conditions in a certain area must be based on the human factor, surroundings and seasonal and anopheline factors, the author briefly discusses these subjects, dwelling particularly on the anopheline factor.

"From larvae breeding and the capture of culicine adults in the Gondar zone (Ethiopia), the author had following results: several specimens of *Dipterae* (gen *Culex*) and only two *Anopheles* *A cinereus* and *A demeilloni*. None of these are known to be malaria vectors. The author therefore thinks that malaria control in Gondar is unnecessary."

CIUCA M, BALIFF, L & CHELARESCO, M Formes dégénérées de sporozoïtes dans l'infection expérimentale d *A maculipennis* v *atroparvus*, *P vivax* et à *P falciparum* [Abnormal Forms of Sporozoites in Experimental Infection of *A maculipennis atroparvus* with *P vivax* and *P falciparum*]
Liber Jubilans J Rodham (Soc Belge Méd Trop, Brussels) 1947, Dec, 131-46 2 figs

During the last 15 years work on experimental malaria has been carried out at the Socola station in Rumania. The authors used a Madagascar strain of *P vivax* and a local strain of *P falciparum*. Transmission to cases of G P I was effected by blood inoculation and by sporozoites from *Anopheles maculipennis* var *atroparvus*. The sporozoite infections resulted from (a) mosquito bites, (b) bites plus intravenous inoculations of glands, and (c) intravenous inoculations of glands alone. The second method was slightly more successful but about 90 per cent of all the patients developed the disease.

Fifty per cent of 774 *Anopheles*, fed on *P vivax* carriers, became infective. 17.7 per cent of these infections exhibited abnormal sporozoites.

Fifty-five per cent of 688 *Anopheles*, fed on *P falciparum* carriers, became infective. 32.4 per cent of these infections exhibited abnormal sporozoites.

These modifications in the appearance of the sporozoite were primarily a thickening of its body and the conversion of its chromatin into a bloated mass lying in a colourless vacuole. The shape undergoes various contortions. The abnormalities bore no apparent relation to temperature or humidity variations, nor to season.

[Examination of the protocols reveals that abnormal forms were commoner among the sporozoites which first reached the glands, and that in the older mosquitoes, degeneration was less likely to occur.] P. C. C. GARHAM

SHORTT H. F., GARHAM I. C. C., CUSTELL, C. & SMITH P. C. The Pre-erythrocytic Stage of Human Malaria, *Parasitology* *Epid. Med.* 1948 Mar 20 547

The observations on *Plasmodium cynomolgi* by SHORTT & GARHAM of the pre-erythrocytic stage of development in the liver of the monkey led them to suspect that *Plasmodium vivax* would be found to have a similar cycle in the liver [this *Bulletin* 1948, v 45 368]. Accordingly a large number of *Anopheles maculipennis atroparvus* infected with *P. vivax* were fed on a patient at the Horton Hospital for Mental Diseases on two successive days. In addition an emulsion of infected salivary glands was injected intravenously. Seven days after the first feeding of the mosquitoes a biopsy was performed under local analgesia and a portion of liver removed for examination. In it were found plasmodial masses studded with chromatin particles very similar to those previously found in the monkey infected with *P. cynomolgi*. The masses measured up to 4μ in diameter and in some cases had the vacuoles noted in *P. cynomolgi*. There seems to be no doubt that the bodies are the pre-erythrocytic stages of development of *P. vivax* in man. The material is being studied and a further report is promised. C. M. HEWITT

HUFF C. G. Periodos excentricos de los parásitos de la malaria. [Erythrocytic Stages of Malaria Parasites.] *Medicina, Mexico* 1948, Jan. 25 28. No. 548, 23-33.

A review

BRADLEY L. C. Note sullo sviluppo dell' *Anopheles sacharovi* sulla costa del Veneto [The Development of *Anopheles sacharovi* on the Venetian Coast. *Rivista Parassiti* Rome 1947 Dec. 8, No. 4 197-203. (10 refs. English summary (8 lines))

The highly malarious area in the north-east of Italy is limited to a coastal strip some 10 to 15 km. in width from Ravenna to Trieste. This corresponds to the area of distribution of the chief vector *A. sacharovi*. It is generally assumed that this species has a marked partiality for saline water in which to lay its eggs and that the presence of saline marshes and lagoons in this area explains the high incidence of malaria. The author's observations do not confirm this supposition. He found *A. sacharovi* breeding in water with a very low saline content. NORMAN WHITE

THOMSON R. C. Mourhead. Studies on *Anopheles gambiae* and *A. melis* in and around Lagos. *Bull. Entom. Res.* 1948 Feb. v 38, Pt. 4 527-58. 1 map 3 text figs. & 5 figs. on 1 pl. 123 refs.

The presence of an additional dark band on the palps of about one-third of female adult *Anopheles melis* in the Freetown area enables an estimate of *melis* population possible without recourse to the laborious method of

distinction to distinguish *gambiae* from *melas*. This does not apply in the Lagos area, as the number of 4-banded *melas* is too small, of 1,200 egg batches examined, 99.7 per cent were readily distinguishable into *gambiae* or *melas*.

The seasonal incidence of *melas* and *gambiae* in houses is tabulated for villages, on the coastal strip of the mainland to the north and west of Lagos Island for Lagos Town and for creek villages to the east. In the first group numbers are about equal on the coastal fringe, but *melas* fades out at a short distance (1 mile) from the coast, in Lagos town, on an island, *gambiae* is predominant, in the third group to the east, which is associated with mangrove swamp, *melas* is the most abundant. Despite these generalizations, catching stations within a short distance of each other may have widely different mosquito populations. The abundance of *melas* is mainly determined by tidal movements which are variable and unpredictable when compared to the Freetown estuary. In contrast, the abundance of *gambiae* is related to the rainfall, a great reduction in numbers occurring in the dry season, November to March. Finally, in any one village the seasonal incidence of both mosquitoes may follow entirely different courses in consecutive years.

The sporozoite rate of *gambiae* (10 per cent) is consistently higher than that of *melas* (3.5 per cent). Peak production of *gambiae* is associated with a lowered sporozoite rate, but in the last three months of the year when the *gambiae* population is low, the rate is higher and may reach 29 per cent. The sporozoite rate of *melas* tends to conform to the numbers of females present in houses and is comparable to the Freetown Estuary rate of 4.2 per cent. [See TREDRE, this *Bulletin*, 1947, v 44, 488]. Observations on resting places, both indoor and outdoor, indicate that *gambiae* in the gravid state made use of the house to a much greater extent than did gravid *melas*, in one village it was estimated that through the favourable six months of the year, *melas* made use of outside resting places to 10 times the extent that *gambiae* did. The degree to which *gambiae* or *melas* favour outside resting places is of considerable importance in relation to the use of residual insecticide in houses as a control measure.

The movement of mosquitoes in and out of houses was investigated by the use of experimental huts fitted with a special window trap, this method resulted from the observation that exterior waning light is a powerful attraction to mosquitoes indoors. It was noted that 90 per cent of blood feeding by *melas* and *gambiae* took place after midnight, the period of greatest activity being between 4 a.m. and dawn, 43 per cent of *melas* and 26 per cent of *gambiae* which had entered and fed left by dawn the same night. In the case of *melas* which remained in the hut, all gravid and 70 per cent of half-gravid females left at dusk.

The author was successful in getting swarming, mating and fertilization of *melas* and *gambiae* to take place in 1 ft.-cube cages. Data of cross-fertilization experiments are quoted, hybrid males were sterile.

The breeding areas of *melas* are very difficult to localize and the whole tidal swamp area covered with *Paspalum* is suspect, the comprehensive nature of the tidal swamp reclamation should eliminate all potential breeding places [GILROY and CHWATT, this *Bulletin*, 1945, v 42, 786]. Breeding areas of *A. gambiae* are the typical open shallow water collections, which include almost dry wells, rain pools and puddles and sedge swamps. The last-named may be just below high water mark and prolific breeding will cease abruptly if a fortuitous tide floods the area. In Lagos Town, the steady progress in street drainage and swamp filling has practically eliminated breeding places. However, the author draws attention to the instance of a single small garden-compound producing in the rainy season a *gambiae* output sufficiently enormous to affect a whole corner of the city and nullify good work in process elsewhere.

(There is no reference to the possibility of the invasion of Lagos Town by malarial from across the surrounding waters and the evidence of this paper suggests that after the extensive swamp reclamation measures in the district, the town and port may be kept relatively free of malaria vectors by a vigilant sanitary staff.)

R. Ford Trel.

SCHWETZ, J. Sur le lac Tumba. Notes géographiques, entomologiques et médicales. (Moustiques et paludisme tschads et trypanosomiase.) Lake Tumba. Geographical, Entomological and Medical Notes: Mosquitoes and Malaria [Tsetse Flies and Trypanosomiasis.] Inst. Roy. Colonial B. et. Bull. des Sciences 1917 v. 18, No 2, 482-511 1 map & 3 figs. on pl.

Lake Tumba lies near the l ft bank of the River Congo about 100 kilometres south of the Equator. A winding channel about 15 km. long unites the waters of lake and river. Such little current as is manifest in this channel is towards the lake in the rainy season and towards the river when the water is low. The lake is about 43 km. long (north-south) and about 22 km. broad. Its shores are indented by very numerous bays and capes. Several rivers discharge into the lake the two largest being the Lola into the south of the lake, and the Ngombe into the north-east.

The author spent three weeks investigating conditions on the shores of Lake Tumba, making his headquarters at Bikoro about the middle of the eastern shore. A motoring road, 128 km., joins Bikoro to Coquilhatville which lies on the Equator almost due north of the lake.

The banks of the lake are for the most part high and gently sloping wooded and without grassy or marshy edge favourable to mosquito breeding. In such places mosquitoes are almost non-existent. But on certain small bays, near villages swampy conditions near the mouths of small streams are productive of mosquitoes: these are still more numerous near the mouths and along the banks of the larger rivers.

A. taeniorhynchus and *A. fuscipes* were the most prevalent *Anopheles* along the shores of Lake Tumba: these two species are in general rather rare in this part of the Congo and neither has been incriminated as a vector of malaria. *A. merus* var. *merus* the predominant anopheeline at Coquilhatville was rare as was *A. fuscipes*. *Aedes aegypti* was not found. *Mansonioides* were very rare.

G. sinuipalpis was rare along the shores of the lake but very prevalent along the banks of the rivers that flow into it. Several specimens of *G. sinuipalpis* were also captured.

S. m. m. circumscriptum was very prevalent along the shores of the lake they bit during daytime but were most active towards evening. Phlebotomids were also plentiful. *Ph. africanus*, *Ph. africanus* as *niger*, *Ph. decipiens* and *Ph. setiferus*.

The blood of 448 inhabitants of four lakeside villages was examined. This showed malaria to be endemic: parasite rates were high but the number of parasites was low. *P. falciparum* was by far the most prevalent species. *P. vivax* was only found in two films. *Leishmania* *Leishmania* *Leishmania* was frequently encountered. *Leishmania* occasionally.

The author found a considerable number of villagers who were undergoing treatment for sleeping sickness or who had been treated but little or no evidence that they were or had been infected. The diagnoses had been made on altogether insufficient evidence. In only one of the 448 individuals examined, thick drop and smears were trypanosomes discovered: he was a schoolboy in the Catholic Mission School at Bikoro. Sleeping sickness exists in this region but cases are extremely rare.

Norman White

MILLER, A., BURGESS, R. W. & CARPENTER, S. J. **Potentialities of Transportation of Exotic Anophelines by Airplane** *J National Malaria Soc* 1947, Dec, v 6, No 4, 227-43 [27 refs]

The number of aeroplanes entering the United States of America each year is estimated to be 35,000, or nearly 100 per day. This volume of air traffic is increasing and the time spent on journeys is being reduced, so that very soon no place will be more than two days' flight from the U.S.A. The bulk of the traffic at present comes from Latin America and it might be expected that the greatest danger of importing mosquitoes lies in that quarter, but from the climatic point of view, Europe and the non-tropical areas correspond more closely with conditions in the U.S.A. as a whole, and it may be more likely that species transported from such places would be more easily established.

The authors review the history of the development of international air traffic and discuss the practical application of the "International Sanitary Convention for Aerial Navigation". Figures are quoted from reports showing, for example, that in the year July 1st, 1944 to June 30th, 1945, 1,418 mosquitoes (158 alive) were among 24,930 insects found on 12,367 aircraft. There were 1,339 culicines (142 alive) of 21 species and 79 anophelines (16 alive) of 9 species. The identified anophelines were *Anopheles albimanus*, 10 alive out of 34 found, *A. pseudopunctipennis*, 2 alive out of 4, *A. quadrimaculatus*, 3 alive out of 5, *A. punctipennis*, 1 living, *A. crucians*, 19 dead, and 1 dead specimen of each of the following, *A. grabhami*, *A. maculipennis aztecus* (?), *A. neomaculipalpus*, and 4 *pharoensis*. The last-named and one Indian culicine are the only Old World species in the reports that are not already present in the U.S.A.

It is thought that not more than 10 per cent of mosquitoes are detected in the planes, and the authors speculate on the hypothetical number of exotic mosquitoes likely to be imported in one year and arrive at the following figures for 100 aircraft: 115 mosquitoes (13 alive), 64 anophelines (13 alive), and 1 exotic species including 0.3 to 0.6 exotic anophelines. At this calculation 35,000 aircraft would bring in 350 exotic mosquitoes of which 100 to 200 might be anophelines not already recorded in the States or 10 to 25 living anophelines per year, but during the last three years, no viable anopheline has been detected in the incoming aircraft, owing to the efficiency of the preventive measures. Nevertheless, in spite of the small chances of importation of these mosquitoes, prudence and experience demand a continuance and extension of mosquito control around airports, and the disinsectization of the aircraft. The efficiency of insecticides is improving, as also are the methods of application, and the likelihood of new malaria vectors becoming established in the United States remains, in the opinion of the authors, a potential problem but not an acute one.

H. S. Leeson

GIGLIOLI, G. **An Investigation of the House-frequenting Habits of Mosquitoes of the British Guiana Coastland in relation to the Use of DDT** *Amer J Trop Med* 1948, Jan, v 28, No 1, 43-70, 6 figs & 1 graph

In the first quarter of 1945, SYMES and HADAWAY [this *Bulletin*, 1945, v 42, 785] initiated in British Guiana the spraying of houses with DDT. Progressive expansion of this work necessitated preliminary mosquito surveys of which this paper is descriptive. These were confined to the coastal zone, the topography and meteorology being briefly referred to. The precise localities selected for description can be taken as prototypes of ecological conditions prevailing in urban, suburban, village and rural areas of the coastland of British Guiana. [Several excellent photographs are included.] Monthly morning mosquito captures in houses are tabulated for each locality for periods varying from two

to fifteen months. In one locality an experimental hut enabled 24-hourly catches to be recorded—a Shannon down trap with animal bait was used in this area primarily to estimate the *A. gambiae*'s population, but a table of all captures is given.

The mosquito species encountered were nine in number of which *A. gambiae*, *A. albopictus* and *C. univittatus* (species not determined) were rare. *Aedes triseriatus* and *Aedes albopictus* rarely frequent houses. *Aedes aegypti* is subject to control measures. *Culex fatigans* and *Anopheles* sp. accounted for 86 and 28 per cent. respectively of all captures. *Meiobes* varied in different localities. A description is given of the habits, breeding places, etc. of each of the above mosquitoes.

The average *A. darlingi* (the malaria vector) catch per room is as follows—

| Locality | Surroundings | Mosquito Catch per room |
|---------------------------------|--|-------------------------|
| Lesignan (East coast) | Irrigated cane lands | 34.7 |
| Triumph village (East coast) | Irrigated cane lands, inland rice fields and provision gardens | 46.1 |
| Moa Repos pasture (East coast) | Open ventilated front land pastures and rice fields | 0.96 |
| Lodge village | Georgetown suburb | 1.05 |
| Worthingtonville | Georgetown city ward | 0.23 |
| La Grange (West bank, Demetara) | Irrigated inland rice fields and provision gardens | 22 |

The author concludes that the highly domestic biting and resting habits of *A. darlingi* and *Aedes aegypti* render the prospects of control by DDT house-spraying (as a residual insecticide) excellent.

Culex fatigans is variable in its biting and resting habits and it is expected that this control method will have little effect on the total incidence.

R. Ford T. Cole

LEICHTZ G. Citomorfologia e dinamica medulare nelle prime fasi della malaria indotta. (The Bone Marrow in the Early Stages of Induced Malaria. *Riv. di Malariologia* 1947 Dec. v. 23 No. 8 257-62.)

The English summary appended to the paper is as follows—

The author studied the behaviour of the haemopoietic marrow in 8 progressive paralytic patients inoculated with *Anopheles* (5 *P. vivax* and 3 *P. falciparum*). The sternal punctures were carried out in series, beginning before the inoculation and continuing until the onset of the disease.

The author having thus established the starting ground (anatomical functioning of the marrow in the progressive paralytic patients) studied the results following inoculation and observed that during the incubation period and the very first phases of the disease the marrow assumes a prevalently erythroblastic orientation, without a constant and prevailing reaction of the reticulum-endothelium.

HECHBERG J & HENNING D. Studies on Liver Damage in Acute Malaria. *Trans. Roy. Soc. Trop. Med. Hyg.* 1948 Jan. 41 No. 4 535-64 graphs. (23 refs.)

The authors have investigated the Weltmann reaction in 96 cases of naturally acquired *P. vivax* and *P. falciparum* malaria. This reaction measures the

coagulability of the patient's serum in solutions of calcium chloride, this is apparently governed in some way by the globulin content. Sixty-six cases showed increased coagulability. Of these, a high percentage showed changes in cephalin-cholesterol and cholesterol ester fractions of the serum, but there was no correlation between the degree of this reduction and value of the Weltmann reaction, red cell count or sensitivity of the erythrocytes to lysis in bile solution [MER *et al* this *Bulletin*, 1941, v 38, 562]. On the other hand, there was a close relation between changes in the Weltmann reaction (a shift to the right, i.e., coagulation of serum in lower calcium chloride concentrations than normal) and the sensitivity of the erythrocytes to lysis in bile solution.

According to the authors, the results of the Weltmann reaction and the Chorné test (both of which are dependent on certain serum globulins) indicate hepatic damage, since the globulins are synthesized in the liver. Kleeberg claims that "since in all acute haemolytic anaemias the W R (*sic*) quickly shifts markedly to the right, a sudden shift" (to the right in the Weltmann reaction) "in malaria is probably indicative of imminent blackwater fever."

[It would be more profitable at this stage to investigate quantitatively the changes in plasma proteins which actually occur in malaria (as for example was attempted by DOLE and EMERSON, this *Bulletin*, 1946, v 43, 624) than to multiply tests which appear basically non-specific.]

The authors' habit of referring to the Weltmann reaction as the "W R" is both irritating and confusing.] B G Macgrath

RADVAN, I & APREOTESCI, C. La bilirubinémie paludéenne par rapport à la physiopathologie et à la thérapeutique [Malarial Bilirubinaemia in relation to Pathology and Treatment] *Riv di Malariaologia* 1947, Aug., v 26 No 4 183-90

BYLMEYER, J & WINCKEL, C W F. Induced Malaria for Treatment of General Paralysis. *J Trop Med & Hyg* 1948, Feb., v 51, No 2, 27-33, 2 charts

A centre for the provision of malaria parasites for the treatment of general paralysis of the insane in Holland was started in 1921. This article, by two malarialogists who have studied malaria in the field and at the Psychiatric Clinic in Amsterdam, deals with some of the many problems encountered in connection with induced malaria as employed for therapy purposes. The two species of malaria parasite used are *P vivax* and *P malariae*. *P vivax* is preferable to *P malariae* because it produces the necessary number of chills and is readily controlled by anti-malarial drugs.

It is pointed out that infection is readily produced by infected blood and by infected mosquitoes. One advantage of inducing fever by blood inoculation is that the patients never relapse, but, on the other hand, there is some risk of bacterial contamination by this method, especially when some time elapses between taking parasitic blood from a donor and injecting it into the recipient.

For some time the local indigenous strain was used, but this was not very satisfactory. It was found that with the local strain the incubation period was frequently of long duration, six to nine months. The Horton (Madagascar) strain is now used and is proving more satisfactory. Patients who are found to be immune to *P vivax* are infected with *P malariae* and fever develops satisfactorily as there is no cross immunity between the species. *P falciparum* is not used, as it is considered to be too dangerous. The authors state that the number of patients admitted to their clinic is too few to warrant the employment of three different strains of parasite, [Presumably they mean *species* and not *strains*].

Although *P. malariae* has been employed at their clinic for many years, on only one occasion have they succeeded in infecting the local vector (*An. phaeocephalus* var *abruptus*) in 1935.

Failure to infect patients by direct blood inoculation seldom occurs when patients are inoculated at the Clinic, although many failures take place when estrated blood is sent through the post. It is believed that the reason for failures is that most of the parasites die in transit. The incubation period is longer presumably because most of the parasites have died.

Wherever possible, the patients are allowed to have 10 or 12 attacks of fever with temperatures of 104° F. In such cases relapses are few even when infection is induced by mosquito bites. This, it is believed, is because by the end of the fever period most of the patients have become immune. Often the fever is quotidian (*P. vivax*) but this is easily changed to tertian by giving a single intra-venous dose of neocarsphenamine (75 mgm.) which has a selective destructive action on the half-grown trophozoite.

In the case of the Horton Madagascar strain, compared with the endemic Dutch strain, only half of the dose of this drug is needed to change the fever from quotidian to tertian. It was found that there is a mutual homologous immunity between the Madagascar and the Dutch strains. Even patients who have had natural benign tertian infections in Holland are immune to the Madagascar strain. Primary cases of *P. vivax* malaria usually show two or three days of initial fever. Patients who do not show this initial fever tend to go on to a spontaneous recovery before the desired number of attacks has occurred, owing the ultimate belief to the patients' immunity.

The article concludes with advice to those who employ malaria therapy on the preservation of parasite strains and how to treat the fever after the desired number of attacks has been attained. Reasons are also given why blood films of patients undergoing malaria therapy should be examined frequently during the fever period.

PUTNAM, P. BOYD, N. F. & MEAD, Pauline A. Periodic or Cyclical Recurring Phenomena of Vivax Malaria Infections. *Amer. J. Hyg.* 1947 Sept., v. 48, No. 2, 2-47, 14 figs., 1 refs.]

A statistical analysis was made of data concerning the parasitaemia of 10 white patients with naturally induced *P. vivax* infections (McCoy strain). Each patient experienced a primary attack of at least 3 weeks and a period of latency lasting until the 2nd day after inoculation. Forty patients had recrudescences, 30 had none. The records of each of these two groups were again divided according as to whether the prepatent period ended on an odd or even day. Logarithmic mean parasite counts were computed for each day of the period of observation for each of the four groups, with the data referred first to the day of inoculation and second to the day of first appearance of parasites.

Parasites first appear on an average 1 day after inoculation; the parasite density rises steeply to a peak 1-2 days later and then declines gradually. A significant 12-day cycle was observed in three of the four groups. A 16-day cycle characterized the parasitaemia of 28 patients without recrudescences and with even-day prepatent periods, but when the observed crests of the recurring cycles were synchronized it was found that the parasitaemia of 11 followed 12-day rhythm that 19 followed 16-day cyclical course while that of the remaining six showed no cyclical trend. A significant 16-day cycle was revealed in the parasitaemia of 4 patients extending over 80 days after inoculation.

Either the day of inoculation or of the first appearance of parasites may become the point of reference on which the primary divisions of patients is made on

the basis of prepatent periods The first paroxysm is not a desirable point of reference

Evidence of brood dominance was afforded by the parasitaemia of 15 patients with even-day prepatent periods and no recrudescences, the mean counts were significantly higher on odd days following inoculation Six of these patients had primary attacks predominantly tertian in character with paroxysms on even days

A statistical study was also made of data concerning recrudescences, and their prior remissions of two days or more, of the 40 patients The purpose of the study was to determine whether the days of onset of recrudescences and remissions follow a rhythmical pattern, whether such pattern is related to the cyclical trend of parasitaemia previously determined, and whether their timing shows dominance in the activity of one brood of parasites over that of the other The data were referred to the day of inoculation, the day of first appearance of parasites, and the day of the first paroxysm of the primary attack

A significant 12-day rhythm was indicated by the days of onset of recrudescences In patients with odd-day prepatent periods the clustering of events was most clearly defined when the onsets were referred to the day of first parasites For patients with even-day prepatent periods the rhythm was most evident when the data were referred to the day of first paroxysm A significant 12-day clustering of remissions was evident only for patients with odd-day prepatent periods

Remissions increase in length as recrudescences grow shorter though no significant correlation between their durations was determined Recrudescences averaged 6.2 and 7.2 days in length for the two groups of patients while remissions averaged 5.8 days for each Thus the length of the two intervals combined was 12 and 13 days respectively

Paroxysms initiating the primary attack and those immediately preceding and following remissions are as likely to occur on odd as on even days, this affords no evidence of the dominance of one or other brood of parasite

The authors offer no explanation of the cyclical phenomena observed These may be due to some unknown aspects of the schizogonic cycle of the parasites or to intermittent activity of the host's defence mechanism *Norman White*

KULCSAR D D Effect of Malaria on Pregnancy *Canadian Med Ass J* 1947, Oct, v 57, No 4, 332-7 [17 refs]

A study of the effects of malaria on the course of pregnancy, based on admissions from May 1st, 1946 to the end of April 1947 to the Obstetrical Department of the Kweilin Provincial Hospital, the admissions totalling 360 cases The Province of Kwangsi, with its capital Kweilin, is stated to be one of the worst malarial districts in China No accurate data are available, but it is estimated that at least 50 per cent of the population suffer from malaria

In the series under review, 59 cases (17 per cent) showed a positive blood smear on examination, while 173 gave a definite past history of malaria (48 per cent of admissions) Eight patients were treated on clinical signs alone Of 59 patients definitely proved to be positive on blood examination, 19 had premature labour (period of gestation not given) and 9 had threatened or incomplete abortion, i.e. 48 per cent of abnormal cases compared with 18 per cent of abnormalities in the so-called malaria-free group (120) cases

The type of infection in the 59 positive cases was *P vivax*, 26 (44.3 per cent), *P falciparum*, 33 (55.7 per cent), *P malariae*, nil one case of mixed *vivax* and *falciparum* infection From a study of the literature and from

following up some of his cases, the author believes in the occurrence of congenital malaria.

The author thinks that a past history of malaria has no adverse effect on the course of pregnancy except as regards the possibility of recurrent *P. vivax* infections being rather more liable to relapse than *P. falciparum* (55 as compared to 45 per cent.). Of the 59 blood positive cases, 56 were recurrences and only 9 were primary infections. It is thought that most of the recurrences would have been prevented, most of the premature labours continued to term and some of the stillborn infants born alive had suppressive anti-malarial medication been consistently used.

While the author agrees that the most thorough search should be made for any possible cause of fever he suggests that there should be no delay in administration of mepacrine or quinine where there is any clinical suspicion of malaria. Leucopenia and relative mononucleosis are regarded as valuable signs of a malarial infection.

The Kahn test was positive in 11 per cent. of cases with positive blood smear or a past history of malaria, as against 7 per cent. in malaria negative cases.

MAXSON BURN (*Maxson's Tropical Diseases* 12th ed. 1945) considers that malaria *per se* is a far more potent oxytocic than any drug. However he recommends care in giving quinine as if it is administered in large doses it may sometimes cause miscarriage but ACTON as cited in the same work, thinks that miscarriage can only be caused by doses of quinine large enough to poison the patient. [The reviewer in the course of a fairly wide experience has come to the same conclusion, in fact he has found that the most efficient abortifacient is a smart attack of subtertian malaria left untreated for a few days.]

Mepacrine was found to be well tolerated by pregnant women in relatively large doses and is replacing quinine in pregnancy although opinions still differ as to its efficacy compared with the latter drug. With the usual plan of dosage an effective plasma level was found to be attained more rapidly with quinine than mepacrine.

The author treated 30 cases with quinine and 20 with mepacrine. Fifty per cent. of cases treated with mepacrine were controlled after one febrile attack, but only 22 per cent. of those treated with quinine were so controlled. No untoward effects were experienced with either drug but it is considered that paludrine will probably be the drug of choice in the near future. Contrary to previous reports, the author does not think that malaria is a serious predisposing cause of toxæmia.

CHEN G. & GEILING, E. M. H. The Acute Joint Toxicity of Atabrine, Quinine, Hydroxyethylapocuprine, Pamaquine and Pentaquine. *J. Pharm. & Exp. Ther.* 1947 Oct. v. 91 No. 2 133-9 5 figs

Combinations of quinine and plasmoquine (pamaquin) were used in the treatment of *P. vivax* malaria by SEXTON & BRIDG (this *Bulletin* 1929 v. 28 11) soon after the discovery of the latter drug. Atabrine (mepacrine) and plasmoquine were similarly used by MUMFORD & FLEMING (this *Bulletin* 1932, 29) in the treatment of malignant tertian malaria. The present author has investigated the acute joint lethal toxicities for mice of certain pairs of the drugs named in the title. Mice of 18 to 24 gm. weight were used in groups of 20 for each test and were injected intraperitoneally with a definite volume of solution based on body weight. It did not materially affect the results whether the two drugs were given in one solution or separately. Deaths were recorded after

an observation period of two days Quinine and atebrin acted independently and similarly as regards toxicity, so also did quinine and hydroxyethyl-apocupreime In the case of atebrin and pamaquin, the lethal effect of the latter was not influenced by a sublethal dose of the former, indicating that the two substances act independently but in different ways The mortality when atebrin was used in the lethal range was, however, greater than expected Quinine with plasmoquine and also quinine with pentaquine (chemically related to pamaquin) displayed a synergistic action as regards toxicity A similar synergistic action of these substances was displayed in their therapeutic action on avian malaria The explanation suggested is that quinine and pamaquin may act on different stages in a vital enzymatic process *J D Fulton*

ANDREWS, W H H, GALL, D & MAEGRAITH, B G Studies on Synthetic Antimalarial Drugs XIX The Effect of Therapeutic Courses of Paludrine on the Relapse-Rate of Vivax Malaria *Ann Trop Med & Parasit* 1947, Dec, v 41, Nos 3/4, 375-9, 1 fig

The relapse rate in *P vivax* infections after administration of a therapeutic course of atebrin (mepacrine) consisting of 200 mgm thrice daily for 2 days followed by 100 mgm thrice daily for 10 days to patients having clinical attacks, was compared with that of two similar groups of patients treated with paludrine The dosages of the latter were 500 mgm twice daily for 14 days and 50 mgm twice daily for 14 days respectively The cases were not specially selected, infection having been acquired by most patients in the Far East and by a few in the Mediterranean A follow-up of 92 cases was made for 6 months, by means of postcards For assessment of results, only those relapses were considered which occurred within this period after treatment The results with paludrine were similar to those obtained by JOHNSTONE [this *Bulletin*, 1947, v 44 284], and the relapse rate was approximately the same on the three different dosage-schedules In a separate experiment, patients were given an initial dose of 10 to 300 mgm paludrine and thereafter 100 mgm weekly for six months The follow-up after treatment was again made by post, cards and microscope slides being provided, the latter were to be returned with a thick blood film if relapse was suspected By this means, the follow-up period for 79 patients was not less than 1 year in each case The total number of relapses was 15, and the relapse rate was lower than those rates which followed the dosage schedules described above *J D Fulton*

CHEN, K K & ANDERSON, R C The Toxicity and General Pharmacology of N_1 - p -Chlorophenyl- N_5 -Isopropyl Biguanide *J Pharm & Exper Therap* 1947, Oct, v 91, No 2, 157-60 [10 refs]

The authors have made observations on the pharmacology and toxicity of paludrine in various laboratory animals with results which are summarized as follows

"1 The acute toxicity of N_1 - p chlorophenyl- N_5 -isopropyl biguanide HCl has been compared with quinine 2HCl and quinacrine HCl in mice, rats guinea-pigs and rabbits

2. The biguanide has been repeatedly administered in various doses to rats. No pathologic lesions can be demonstrated, and death from large doses may be attributed to acute systemic effects.

3. The biguanide lowers blood pressure with an acceleration of respiratory rate in anesthetized cats.

4. With the exception of the isolated guinea pig's uterus which contracts by contraction, the biguanide has an inherently relaxing property on the isolated rabbit's uterus and intestine, and the isolated guinea pig's intestine.

5. The action of the biguanide on the blood sugar of rabbits is suggestive of a slight hypoglycemia."

VINE J. M. Malaria Control with D.D.T. on a National Scale—Greece, 1946. [Abridged. *Proc. Roy. Soc. Med.* 1947 Nov. v. 40 No. 13 811-8 (Sect. Epidem. & Stat. Med. 43-50)]

This is a description of a nation-wide attempt that was initiated by UNRRA to eradicate malaria from Greece. DDT was the sole weapon employed. A trial of the ground methods was made in 1945. The resulting fall in malaria incidence and the eradication of insect pests were so satisfactory that the Greek Government allocated £200,000 for the major onslaught in 1946. The organization was based on UNRRA Headquarters at Athens and the Malaria Division of the Athens School of Hygiene. In each of 11 districts into which the country had been divided, there was a Greek malariologist, an American sanitary engineer of the U.S. Public Health Service, Greek sanitary engineers, and Greek inspectors and foremen trained in the technique of preparing DDT mixtures and of spraying. These specialists hired gangs of labourers and trained them to do the actual work. For the eradication of hibernating mosquitoes 5 per cent DDT in either kerosene or Diesel oil was used at 200 mgm. per square foot. In April larvicidal work was commenced. Water accumulations up to 5 kilometres from village or hamlet were sprayed with 5 per cent DDT in Diesel oil. This continued throughout the summer until September 30. Up to November 1 about 100,000 houses and outbuildings were sprayed.

Aeroplanes were used for spraying marsh lands. Eighteen small training planes of the U.S.A.F. trimaster type were employed. The area to be sprayed determined by survey was 113,000 acres at the beginning of the season; this shrank to 80,000 acres during the dry summer. It was sprayed 5 times. DDT 20 per cent in Diesel oil was used for all aeroplane work. Under ordinary conditions, pilot could spray about 17 acres per minute.

The side-effects of DDT spraying were interesting. In Athens in 1946 there was an almost total absence of flies. In addition to the spraying of houses, large garbage dumps near the city were sprayed from the air at intervals during the

summer Sandflies disappeared from the Nea Smyrna suburb of Athens Air-spraying was effective against the *Dacus* fly in olive groves and against a plague of Tene moth in pine and fruit trees A fall in the notifications of dysentery from July onwards may have resulted from a destruction of flies

The incidence of malaria was much below the expected level, comprehensive statistical data are not available It is estimated that some 3,600,000 persons were protected, about 80 per cent of the population at risk The overall cost per head was two shillings

An addendum to the paper enunciates the following conclusions and principles —

(1) Comprehensive data on all aspects of the areas to be dealt with are essentially required in advance

(2) Complete co-operation is required between all sections engaged in the operation, this includes Government, technical and administrative staff and the public, the public must be kept fully informed of developments

(3) The time-factor of anopheline habits must be taken into account e.g., in Greece *A. elutus* and *A. maculipennis* must be attacked in April, while *A. superpictus* may be overlooked until June–July

(4) Where possible, blood, spleens and "baby rates" should be studied over typical bad malaria areas before and just after the season

(5) It is an advantage to make a final onslaught on breeding sites at the end of the season in order to diminish hibernators

(6) It was found that there was little or no mortality among bees where DDT was used after blossom time this compares favourably with mortality from other forms of chemical insect controls on fruit and vegetables On the other hand, when DDT was used in a house where silkworms were breeding, these were inevitably killed

(7) From experience of 6,000 labourers over six months, it is stated that the toxic effect of DDT on human beings is negligible the effect on the skin of kerosene and oil must, however, be taken into account

(8) There are a number of questions still to be answered regarding the activity of DDT, such as the optimum contact time per area the relative value of larvicidal methods and house-spraying, the best agents for preparing emulsions, the optimum *para-para* content of technical grades of DDT, the effects of temperature and storage, and the most suitable containers for DDT much experimental work is still required towards determining the most satisfactory and economic use of DDT in large-scale malaria control schemes

Norman White

AFRIDI, M K & BHATIA M L Malaria Control of Villages around Quetta (Baluchistan) with DDT *Indian J Malarology* 1947, June, v 1, No 2 279–87, 1 folding map

In rural villages in the Quetta district (30°N 67°E) the incidence of malaria is high in the transmission season from mid-July to mid-September A pilot control scheme in a limited number of villages (20,000 population) was instituted in 1946 with the following aims and objects to find —

- Whether malaria in a rural population in Baluchistan could be controlled simply by killing adult mosquitoes by periodic DDT spraying
- Whether the cost *per caput* on such control measures would be within reasonable economic bounds and
- Whether spraying operations could be conducted in a community in which the purdah system (seclusion of women) rendered entry into houses difficult

The villages concerned are described A 25 per cent DDT emulsion concentrate diluted with 9 parts of water gave a spraying solution containing

2.5 per cent DDT. The dosage applied to wall surfaces was estimated to be 1 to 1.5 cc per sq. ft. (25-38 mgm. DDT per sq. ft.). Three distinct groups of villages were treated once by outdoor spraying; the surfaces treated are not defined between July 22nd and August 2nd, four weeks after this first spraying, one group was re-treated indoors, one group outdoors and one group by a combination of indoor and outdoor spraying. The vector mosquitoes were *A. persectus*, *A. culicifacies* and *A. stephensi*.

A table summarizes the quantities of DDT used and man hours expended. The cost of two sprayings amounted to 2.4 annas per rapid, but a single insect application of DDT emulsion would be effective for one malaria season at cost of 1.4 annas exclusive of medical supervision.

The results as assessed by spleen and parasite rates in children in June and September showed a definite effect in lessening the intensity of malaria transmission in two groups of villages whereas in the third group which had been treated by both indoor and outdoor spraying no decrease occurred; this was believed to be due to malaria infections contracted in neighbouring untreated villages. The decrease in spleen rates in the favourable groups were 31 to 38 and 45 to 35 per cent, respectively whereas untreated control villages showed that the usual degree of malaria transmission caused a rise in spleen rate of 36 to 46 per cent between June and September. No insuperable difficulties were encountered in gaining entry into the houses for spraying despite the local purdah system.

HAWKING F. & HUNT R. The Loochi Type of Malaria Parasite in Monkeys. *L'et J. Malarij. J. Rodent.* (Soc. Belg. Med. Trop. Brussels) 1947 Dec. 251-64. 13 coloured figs. on 2 pls. & 3 figs. 20 refs.]

In the blood of a baboon received from the Gambia a malarial parasite identified as *Plasmodium loochi* was found. The parasite occurred as mature gametocytes and ring forms of various sizes. It transpired that the ring forms were immature gametocytes and nothing in the shape of asexual development occurred in the blood. Fresh batches of rings appeared in the blood from time to time. The spherical gametocytes shown on a coloured plate, when mature appear to be extracellular. Batches of *Anopheles quadrimaculatus*, *Anopheles maculipennis*, *Anopheles atroparvus*, *Aedes aegypti* and *Culex molestus* were fed on the baboon. Of 771 mosquitoes, a few oocysts were seen in the stomachs of 3 *Anopheles quadrimaculatus* and one *Anopheles maculipennis atroparvus*. With the appearance of *GAMMA* a description this Bulletin 1947 44 863 of the large schizonts of *P. loochi* the authors examined the liver of the infected baboon and found a number of yellow nodules in the liver. These were sectioned and appeared to be degenerated schizonts. Owing to the absence of schizonts from the liver the authors conclude that the parasite is not a *Plasmodium* but a *Haemofilia*. The paper is illustrated by coloured plates and black and white plates. Stages of schizonts figured are from Gamman sections and smears.

C. M. Wrenn

CRUZ W. O. & DE MELLO R. P. Infecção do macaco sul americano *Sagu* (*Callithrix jacchus* Linnaeus 1758) com o *Plasmodium kneri* (Infectões of the South American Monkey *Callithrix jacchus* with *Plasmodium kneri*). *Mem. Inst. Oswaldo Cruz* 1947 Mar. 45 N. 1 119-1.

The English summary appended to the paper is as follows:—

Infection of the South American monkey *Sagu* (*Callithrix jacchus* Linnaeus 1758) after inoculation with *Plasmodium kneri* has been observed. Intra-nous mass inoculation is being, death in about ten days. With intra-muscular inoculation of smaller quantities of parasites post-mortem cure has

been verified several times. The known 24 hours cycle as well as the morphological characteristics of the *Plasmodium knowlesi* as observed in Rhesus infections, remain the same in the monkey studied.

"The vigor of *Callicebus jacchus* when kept in captivity is definitely less than that observed with Rhesus monkeys, but as its buying cost is thirty times less, it could be considered a useful new experimental animal for malaria research."

MULLIGAN, H W & SOMMERVILLE, T. *Malaria in the Malabar Squirrel* *Indian J Malarology* 1947, June, v 1, No 2, 329-35, 30 coloured figs on 1 pl [10 refs]

The authors place on record observations made on a blood parasite of the Malabar squirrel (*Sciurus indicus malabaricus*). The work was interrupted by the 2nd World War and was never completed. [These authors, however, appear to have made further studies on the same parasite, in the course of the Mammalian Malaria Enquiry—see this *Bulletin*, 1947, v 44, 966. They were again unsuccessful in finding exo-erythrocytic stages. In the latter paper the parasite is referred to as *P. ratufae*.]

The squirrels are found in the dense forests of the Nilgiris, and they live in the upper strata of the trees. Seven out of nine adult animals exhibited the parasites in the blood, chiefly as mature gametocytes. The trophozoites are stated to be scanty and not to occur as small signet-ring forms but occasionally as large rings, later becoming amoeboid and often extremely irregular. No dividing forms were seen either in the blood or in sections of spleen, liver, kidney, lung and intestine. The infected red cells showed no enlargement or stippling. The pigment is dark brown in colour and is very clearly seen in the microgametocyte. This form is characterized by its pale cytoplasm and large nucleus with deeply staining karyosome. Both sexes are slightly larger than the red cell, all trace of which disappears.

The infection appears to be of low pathogenicity, and it is noted that splenectomy failed to heighten the parasitaemia. The infection could not be transmitted by various species of *Anopheles*, *Culex*, *Armigeres* and *Aedes* (*Stegomyia*) mosquitoes. Sub-inoculation of squirrel blood into laboratory animals and monkeys failed to cause infection.

The authors state that this parasite must be identical with that reported from the same locality by Donovan and named by him *P. ratufae*, they point out that the morphology of the parasite of the Annam squirrel, *P. vassali*, Laveran 1905, is so similar, that a better provisional name for the Indian parasite would be *P. vassali* var *ratufae*.

[It seems probable that this haemosporidian belongs to the same category as *H. kochi* of the African lower monkeys [this *Bulletin*, 1947, v 44, 882], *Plasmodium* species of the Palestine bats (MER & GOLDBLUM, *Nature*, 1947, Mar 29, 444), *P. pteropi* of the New Guinea flying foxes [MANWELL, this *Bulletin*, 1947, v 44, 43] and *P. limnotragi* of the Citatunga [VAN DEN BERGHE, *Bull Soc Path Exot*, 1937 v 30, 272]. Exo-erythrocytic schizogony has been described in the first three of these parasites—all in different forms, its discovery in *ratufae* is awaited with interest.]

1 MARSHALL, P B. The Glucose Metabolism of *Plasmodium gallinaceum*, and the Action of Antimalarial Agents. *Brit J Pharmacol* 1948, Mar, v 3, No 1, 1-7, 2 figs [16 refs]

11 ———. The Glucose Metabolism of *Trypanosoma evansi* and the Action of Trypanocides. *Ibid* 8-14, 4 figs [18 refs]

1 The author has investigated the glucose metabolism of *P. gallinaceum* and the effect of antimalarial agents, on lines similar to those of the original

experiments of CHRISTOPHARS & FULTON (this Bulletin 1938, v 35 709) and subsequent authors whose contributions have been regularly reviewed in this Bulletin. Infected blood from chickens containing 70 to 85 per cent of parasitized cells suspended in isotonic buffer was used in Warburg manometers for the measurement of oxygen uptake. When required, accompanying glucose was removed by washing in the same buffer and the desired substrate or inhibitor added. Phosphorus exchanges were measured in these suspensions over periods of 4 to 5 hours during oxygenation. At the beginning and end of experiments, aliquots of suspensions were deproteinized and after centrifugation the supernatant was analysed for glucose, phosphorylated intermediates, lactic and pyruvic acids. In addition to glucose washed parasitized red cells were able to oxidize glycerol, pyruvate, lactate and to a lesser extent succinate and fumarate. Cyanide and iodoacetic acid acted as inhibitors. Quinine and atebria (mepacrine) did not appear to be active inhibitors of respiration, and differences in action were noted only at low concentrations of these drugs in presence of various substrates. Phosphorylation of glucose was more marked in parasitized than in normal red cells. The effect of inhibitors and antimalarial agents on phosphorylating reactions was also studied. The author's results did not agree with those of MOLLER & EVANS (this Bulletin 1948 v 43 1118) in regard to the use of amino-acids as substrates by the parasite or the nitrogen exchanges brought about by it. A possible pathway for glucose metabolism and mode of interference with it by quinine and mepacrine, is outlined.

II. These experiments on the respiratory metabolism of *T. evansi* have in general confirmed the work of previous authors including that of CHAI & GELLING (Proc Soc Exper Biol & Med 1948 v 63 488) who showed that phosphorylation reactions play a part in the metabolism of glucose by trypanosomes. The experimental methods were similar to those described above. Whole blood from mice infected with *T. evansi* was used, or in some cases suspensions of the parasite freed from red cells. The effect of a trivalent and a pentavalent arsenical as well as of representative diamidines, on metabolism was investigated. The chief end-product of glucose utilization was pyruvic acid. In the case of trypanosomes freed from blood constituents, mouse plasma caused an increase in respiration possibly because of the presence of certain nutrient factors. When a number of such nutrients, including pantothenate were added to suspensions, no increase in O_2 uptake was, however, observed. As in the case of other trypanosomes, glycerol was metabolized, but not lactate, fumarate, succinate, glutamate or aspartate. Iodoacetic acid and fluoroacetic acid inhibited oxygen uptake but cyanide only to a slight extent. Trypanosomes were active in this respect to varying degrees. Hexokinase is possibly inhibited by trivalent arsenicals. A scheme is outlined for the possible phosphorylation reactions involved during glucose metabolism by the trypanosomes.

(It is surprising to find in the first paper the statement that Mues & Coggeshall (1941) showed that parasitized red cells were dependent to some extent on glucose and that mannose, fructose and glycerol would replace glucose as a metabolite since the American authors in the paper quoted, write: Fulton (1938) reported that if the blood glucose was removed from the parasite by washing there was a decrease in respiration which could be restored to its former level by the addition of glucose. Fructose, mannose, maltose, or glycerol could be utilized as substitutes for glucose.) J. D. Fulton

TERPLAN L. A. & SUTER L. H. The Effect of Oxygen Tension on *Plasmodium gallinaceum* Malaria in Chickens. *J Infect Dis* 1948 Jan Feb, v 62, No 1 1-4 (fig)

"1. Exposure to oxygen at atmospheric and lower and pressures for periods of 4 to 10 hours daily had no effect on the rate or degree of parasitaemia, the

development of exo-erythrocytic forms, or the survival time of chicks infected with *Plasmodium gallinaceum*

"2 Prolonged daily exposures to oxygen at atmospheric pressure, resulted in a significant decrease in survival time, accompanied during the later stages of the infection by inability of the treated birds to readjust to ordinary air

"3 Oxygen administration, supplemented by quinine therapy, did not alter the course of the infection, and in most cases decreased survival time"

BELTRÁN, E Estudio comparativo de dos plasmodios parasitos de la gallina domestica (*Plasmodium gallinaceum* y *P. juxtannucleare*) [Comparative Study of *P. gallinaceum* and *P. juxtannucleare*] *Rev Inst Salubridad y Enfermedades Trop Mexico* 1947, June, v 8, No 2, 129-38, 1 map [23 refs] English summary

The author compares the two malarial parasites of the fowl—*P. gallinaceum* described by BRUMPT in 1935, and *P. juxtannucleare* first recorded by VERSIANI and GOMES in 1941 [this *Bulletin*, 1942, v 39, 400] from Brazil and by the author in the same year from Mexico. The former is a large parasite producing 24 merozoites and belongs to the Old World, while the latter is a small parasite giving rise to 4 merozoites. The data available for *P. juxtannucleare* are very incomplete, as it has been little investigated

MICKS, D W A Loss of Gametocytes in *Plasmodium elongatum* *J Parasitology* 1947, Dec, v 33, No 6, 499-505, 2 figs [12 refs]

A strain of *P. elongatum* which had been maintained, since its isolation from a field sparrow, in canaries (10 passages) and ducks (10 passages) and which gave a parasite rate of 3.6 infected cells per 100 red corpuscles (90 per cent of the parasites being gametocytes) was subinoculated to canaries. After 5 further passages of the duck strain (15 in all) and 4 passages of the canary strain, both strains became free from gametocytes. The two strains free of gametocytes were carried on through many duck and canary passages, but they never returned to normal. Inoculation to a sparrow produced no change. Two other strains started in ducks from canaries and the original canary strain ran a normal course

BLACKWATER FEVER

DAWSON, J & FINDLAY, G M Experiments on the relation of Haemoglobinuria and Anuria with reference to Blackwater Fever *Ann Trop Med & Parasit* 1947, Dec, v 41, Nos 3/4, 306-20 9 graphs [18 refs]

This very interesting paper records the results of experiments designed to determine the effects of injection of haemoglobin or its derivatives in dogs and monkeys

Injection of 3 gm homologous haemoglobin depressed glomerular filtration rate (measured by inulin clearance) slightly in normal dogs and to a much greater degree in dogs which had been bled severely eighteen hours before the injection. The urinary flow was not affected in normal dogs, in the bled animals it was greatly diminished and in some cases ceased. Serial counts of "blocked" tubules in renal tissue showed there was no correlation between the extent of tubular blocking and the clinical result of the injection. On the other hand, the glomerular capillaries were empty in 78 per cent of the bled dogs and

in only 32 per cent. of the normal animals. The authors concluded that impairment of the glomerular filtration and not blocking, was the basis of the interference with urinary flow and that filtration was much more seriously affected in the animals which had been subjected to haemorrhage. The oliguria, anuria and reduction in insulin clearance were related to lack of blood supply to the glomeruli as previously postulated by MARGRAITH and FINDLAY (*this Bulletin* 1945 v 4, 12).

The effect of injection of haemoglobin on the blood pressure of dogs was measured directly and it was demonstrated that whereas little change was observed in normal animals, in dogs which had previously been bled, a rise in blood pressure occurred after haemoglobin injection. This rise of blood pressure could be correlated with the absence of blood from the glomerular capillaries. Further experiments showed that from 60 to 90 minutes after injection of haemoglobin into anaemic animals a pressor substance could be extracted from the circulating blood. This substance was not present in blood from injected normal animals. Its production appeared in some way to be related to diminution of the oxygen-carrying power of the blood.

As a result of the chance observation that histidine output in the urine increased for 4 hours after transfusion in a case of toxæmia of pregnancy the output of this amino-acid was estimated in cases of haemoglobinuria in Africans. No obvious correlation was noted between the output of histidine and haemoglobin. In one case of haemoglobinuria which was almost anuric however the histidine excretion was greatly increased during the period of lowest urinary output. Blood removed immediately after the death of this patient was extracted in the same way as the dog's blood and found to contain a pressor substance.

Working on the hypothesis that the pressor substance might be developed in a manner similar to angiotensin, which contains histidine the authors attempted to prepare a pressor substance (sepatensin) with the use of haemoglobin as a substrate and commercial pepsin as the enzyme. The pressor activity of the extract was not constant. If the extract had low free histidine content it was active; if rich in histidine it was inactive.

The authors suggest that failure of histidine excretion in a patient during intravascular haemolysis may be due to the development of some pressor substance in the blood. On the analogy of the renin-angiotensin system, renal anoxia (arising from anaemia) might promote the appearance of an enzyme capable of acting on the globin of haemoglobin to produce a pressor substance possibly a polypeptide. This would constrict the glomerular vessels increase the degree of renal anoxia and diminish the glomerular filtration rate.

HARRISON H E, BLUNTING H, ORLWAY N H & ALBRITCK W C. The Pathogenesis of the Renal Injury produced in the Dog by Hemoglobin of Methemoglobin. *J Exper Med* 1947 Oct 1. 80 v 4 399-416 text figs 3 & 6 figs (1 coloured) on 3 pls 23 r f

This paper deals with the pathogenesis of renal dysfunction in dogs resulting (1) from intravascular haemolysis occurring after passive transfusion and (2) from intravenous injection of solutions of homologous haemoglobin and methaemoglobin. Kidney function was studied by serial estimations of blood urea & plasma creatinine and creatinine clearances. Filtration of fluid through the glomerular membrane was determined by intracapsular administration of ferricyanide and subsequent examination of frozen kidney sections. Direct measurement of renal blood flow was made in two dogs in which one kidney was brought to the flank under anaesthesia without incision on the preclude.

Dogs were found to be resistant to the injurious effects of intravascular haemolysis after exposure to arsine, renal injury was apparent only in cases of extreme haemolysis. Injection of solutions of haemoglobin affected renal function only when the dosage was large. Small doses of haemoglobin injected into four animals made oliguric by deprivation of water caused no appreciable change in plasma urea N. Larger doses in oliguric dogs produced temporary anuria and changes in endogenous creatinine clearance.

The authors quote BING's results (*Bull. Johns Hopkins Hosp.*, 1944, v 71, 161) which showed that severe renal injury followed injection of methaemoglobin in dogs rendered acidotic with ammonium chloride, whereas injection of methaemoglobin or comparable amounts of haemoglobin in normal animals had little effect. They determined the effects of injection of methaemoglobin in normal dogs, dogs made oliguric by deprivation of water, and dogs rendered "acidotic" by intragastric injection of 0.1 N hydrochloric acid.

In non-acidotic dogs with good urinary flow, injection of methaemoglobin in doses of 1 gm per kilo had no effect on renal function. The same dosage in oliguric non-acidotic dogs had serious effects in some cases, including temporary or permanent anuria. In acidotic dogs, in which the urinary output was high, injection of methaemoglobin appeared to have little deleterious effect, in the one animal for which details are given, it produced a temporary diuresis. The authors conclude that in these acidotic animals "although acidosis probably did have some effect in increasing the kidney damage the rate of urine flow was the more important."

Creatinine clearances were measured in some dogs before and after injection of haemoglobin and methaemoglobin. Representative figures are given in text tables.

Injection of haemoglobin in doses of about 4 gm/kilo into two oliguric dogs produced immediate almost complete stoppage of urinary flow. In one animal, this period of anuria was of short duration and was followed by a great increase of urinary flow, up to seven times greater than during the original oliguric state, twenty hours later, the urinary flow was still twice what it had been before injection. Endogenous creatinine clearance was reduced in this dog to two-thirds 60 minutes after the injection and to one-half of the initial figure twenty hours later. In the second dog, there was no post-anuric diuresis and the urinary flow was about double the initial flow twenty hours after the injection, creatinine clearance fell to a trace after the injection and twenty hours later was still only one-sixtieth of the original level.

Injection of methaemoglobin in doses of about 1 gm/kilo into two oliguric dogs produced anuria in both. This persisted in one animal, but in the other urinary flow was restored to the pre-injection level after 90 minutes. In the anuric dog, the creatinine clearance was reduced to a trace. In the other animal, it fell to about one-fiftieth of the original figure about 100 minutes after the injection and was only one-eighteenth four hours later, although the urinary flow had been re-established.

In the one acidotic dog for which details are given, the same dose of methaemoglobin produced a diuresis associated with a reduction of creatinine clearance in the first hour after injection. Subsequently the urinary flow continued at a slightly greater rate than before the injection, but the creatinine slowly fell to one-fifth of the initial figure.

It will be seen from these figures that there appeared to be little relation between the prevailing urinary flow and the endogenous creatinine clearance. Nevertheless, the authors considered the possibility that "a marked reduction of renal blood flow" occurred after the injection of the pigments. They measured renal venous flow directly in two oliguric animals injected with a dose of 1 gm methaemoglobin per kilo. No evidence of reduction of (total)

renal blood flow was found in either animal except after "prolonged anaesthesia and manipulation.

Histological changes in the form of eosinophilic granular precipitates in the glomerular spaces and lumina of the tubules were found within a few hours of the onset of haemoglobinuria in dogs exposed to aniline or injection of haemoglobin or methaemoglobin. With 4 hours of exposure to aniline and two hours after injection of the pigments "masses of granular yellow brown refractive material and well formed casts were found in the loops of Henle distal convoluted tubules and collecting tubules. In severe cases of haemoglobinuria, hyaline eosinophilic droplets which the authors considered to be haemolysis were found in the epithelium of the proximal convoluted tubules. By 36 to 48 hours after the onset of haemoglobinuria, coagulative necrosis of the epithelium of some of the proximal convoluted tubules was evident. Later signs of regeneration of epithelium appeared and granules containing free iron were found in the epithelial cells. After 3 or 4 days "radial zones of tubules containing casts, alternating with sections free of casts" (often with dilated tubules) were seen. Injection of ferrocyanide showed that filtration through the glomerular membrane had occurred even in apparently blocked tubules. The material filling the lumina of the tubules was identified as mainly methaemoglobin in concentrated solution of gel-like consistency. The number of casts per unit area of cortex and medulla was determined. The degree of impairment of renal function was greatest in those animals in which casts were most numerous, and least in those in which casts were few. In four animals, renal insufficiency was present in association with only a small number of casts and in these no anatomical basis for impaired function was found.

The authors conclude that "severe and persistent impairment of kidney function results in dogs from intra-vascular haemolysis after exposure to aniline and from intra-venous injection of solutions of homologous haemoglobin and methaemoglobin. They consider the evidence presented in their paper shows that obstruction to urinary flow through the tubules is an important factor in the early reduction of kidney function. The material in the lumina was a concentrated solution of methaemoglobin and there was no evidence of the formation of pigment insoluble at the pH of urine (after methaemoglobin injection the pH of the urine rose in some animals at the beginning of haemoglobinuria). Injury to the epithelium of the proximal convoluted tubules occurred last after injection of methaemoglobin, haemoglobin or following exposure to aniline. Such epithelial damage probably contributed to the persistent severe depression of renal function.

Direct measurement of renal plasma flow in two dogs did not confirm the observation of other workers who held that injection of haemoglobin caused reduction in renal blood flow. (In these experiments the authors injected methaemoglobin.)

(In coming to their conclusions, the authors have had the advantage over the reader in that they have had access to all the protocols of experiments. The information provided in the text is often inadequate. For instance, the table illustrating the correlation between the number of casts, histological changes in the proximal tubules and evidence of impairment of renal function, gives no indication of the dose of aniline or methaemoglobin used. It is thus not possible to see what relation existed between the dose and the severity of the lesions, which considerably weakens the argument. Similarly the evidence provided concerning changes in creatinine clearance is meagre and inadequate from the point of view of the conclusions drawn. In the experiments quoted in the tables there appears to be little relation between rate of urinary flow and the changes in creatinine clearance. The acknowledgment that the urinary flow was an important factor in modifying the effects of methaemoglobin injection

in acidotic dogs, might be a useful argument in favour of the view that the pathogenesis of renal injury of this kind is related to the glomerular blood flow

The two experiments in which renal blood flow were measured show a reduction in total flow some time after the injection of methaemoglobin, in one case after the re-establishment of oliguric flow, in the other during anuria. It is possible to interpret these results as the authors have done, provided the surgical interference and transposition of the kidneys is disregarded, in terms of no reduction in renal flow following the injection. It should be noted, however, that this refers only to total flow and has no reference to the flow through the cortex, which, for all the evidence provided here, may as well be shunted to the medulla as not. This paper leaves us much where we were.]

KHO LIEN KENG Een geval van zwartwaterkoorts met cyanose (methaemoglobinaemie), waarschijnlijk door plasmochine [**Blackwater Fever and Cyanosis of Plasmochine Origin**] *Med Maandblad Batavia* 1948, Jan, No 18, 342-7 [30 refs]

Plasmoquine has certain advantages by its gametocidal action in malaria therapy, but is undoubtedly toxic. The problem of the cause of blackwater fever is linked in the literature with malaria, quinine and plasmoquine. It is now more than twenty years since plasmoquine was announced (1926) as a drug for use and, in the light of what is now known of its toxic character, it is astonishing to learn that, originally, it was given in a dose of even 250 mgm daily. The present article gives a useful historical account of the subject as introduction to the author's own case of blackwater fever with cyanosis (methaemoglobinaemia). The patient was a young Chinese of 17 years who came for consultation with fever which had started the day before. It was not surprising that as he lived in Batavia and suffered regularly from 3 to 4 attacks of malaria every year, a blood film showed the presence of tertian malaria schizonts. He was given a prescription for 300 mgm. quinine bisulphate four times daily for five days and the temperature fell immediately. Five days after stopping treatment the fever, in this subject of chronic malaria, recurred and he was now given 300 mgm quinine together with 10 mgm plasmoquine, both three times daily. Four days later he reappeared still with fever, looking cyanotic and passing dark red urine. Other symptoms were vomiting, headache, cough and general malaise but no enlargement of the spleen. The blood serum was dark brown and gave the spectrum of methaemoglobin only, oxy- and sulphaemoglobin being excluded. There was no direct van den Bergh reaction, but the indirect reaction was obtained on two occasions. After the patient's admission to hospital, the haemoglobinuria lasted 3 days, the cyanosis a week and jaundice 10 days. His temperature fluctuated between 102° and 105.8°F and he was occasionally delirious. A thick blood film showed no parasites. No albumin, no sugar, but much urobilin were present in the urine. Treatment consisted of vitamins, fruit and fluid. Diuresis was good. A blood transfusion of 250 ml was followed by a pyrexial reaction.

Differential diagnosis lay between blackwater fever and plasmoquine toxæmia. "It is not improbable that sensitization by previous malarial attacks and plasmoquine poisoning are contributory to the development of blackwater fever."

W F Harvey

renal blood flow was found in either animal except after "prolonged anaesthesia and manipulation.

Histological changes in the form of eosinophilic granular precipitates in the glomerular spaces and lumina of the tubules were found within a few hours of the onset of haemoglobinuria in dogs exposed to aniline or injection of haemoglobin or methaemoglobin. VAUCEL, M & CECCALDI, J Les anciens trypanosomes se reinfectent-ils ?
[Do Former Patients with Trypanosomiasis become infected a Second Time ?]
Liber Jubilaris J Rodhain (Soc Belge Méd Trop, Brussels) 1947, Dec, 395-409 [10 refs]

Four patients are described who were discovered during a routine examination to be infected with trypanosomes Their general clinical condition was good and there was no evidence of infection of the nervous system They were treated with atoxyl, tartar emetic or Fournieu 270 and followed up by examinations every 6 months After 8 to 12 years they were found to be infected once again, but the infections responded readily to the usual treatments Three other patients, who had applied for treatment owing to their symptoms, were treated with atoxyl-tartar-emetic, tryparsamide or Fournieu 270 Five to eight years later, they were found to be infected again, they responded readily to further treatment The interpretation of these cases is discussed Five or more of the patients may have been reinfected On the other hand, all the cases may represent reactivation of the infection after a prolonged latent period The evidence is insufficient to decide which of these interpretations is correct

BUCK, Margaret Persistence of the Parabasal Body in a *p*-Rosaniline Resistant Strain of *Trypanosoma brucei* *Proc Soc Exper Biol & Med* 1948, Jan, v 67, No 1, 77-9, 1 fig

"A *p*-rosaniline-resistant modification of *T brucei* is described in which—contrary to the experience with other trypanosome strains—the parabasal body persisted The strain also failed to show the overlapping resistance to 6,6'-ureylene [4-amino-2-methyl-quinolone] which could be demonstrated in *p*-rosaniline-fast strains of *T equiperdum*"

VAN HOOFF, L, HENRARD, C & PEEL, E Observations sur le *Trypanosoma brucei* produisant des infections naturelles dans une région infestée de *Glossina palpalis*, en l'absence de *G morsitans* [Observations on *T brucei* producing Natural Infections in a *Glossina palpalis* Region, in the absence of *G morsitans*] *Liber Jubilaris J Rodhain (Soc Belge Méd Trop, Brussels)* 1947, Dec, 359-80 3 figs [11 refs]

Description of three strains of *T brucei*, from natural infections in a dog, pig and goat, isolated in the western region of the Belgian Congo, where the only important vector is *Glossina palpalis* With these strains cyclical and mechanical passages were carried out through various mammals, including man

Both in natural and experimental infections of pigs, *T brucei* was more abundant in the blood than in the case of *T gambiense* infections, the number of parasites gradually diminishing until the animals recovered spontaneously after periods up to 15 months Attempts to reinfest the pigs with *T gambiense* failed but were successful with *T rhodesiense* It is suggested that in *palpalis* areas the pig probably serves as a reservoir of *T brucei* In goats, *T brucei* produced acute or subacute infections, terminating fatally in from one to seven months, with symptoms of encephalitis In dogs the infection ran an acute or subacute course, with the characteristic symptoms of keratitis, on account of

TRYPANOSOMIASIS

McLITCHIE J. L. The Control of Sleeping Sickness in Nigeria. *Trans. R. Soc. Trop. Med. & Hyg.* 1948, Jan., v 41 No. 4 445-70 4 maps & 9 figs. [35 refs.] Discussion 471-80 (HOLLINS C. TORDA H. W. RAE, Ullva DUGGAN A. J. BUXTON P. L. CHESTERMAN C. C. MACDONALD, G. MANSON BARR, P. McLITCHIE (in reply)).

The author has divided his account of the control of sleeping sickness in Nigeria into several parts: the distribution of tsetse flies, drug resistance of trypanosomes, incidence of the disease, characters of the disease, treatment, prophylaxis and control. The paper therefore contains more than its title indicates, and is in fact, a very comprehensive statement of the whole position, written by a man who has been very actively implicated in the work.

The earlier sections of the paper are themselves largely accounts of work done and opinions expressed by other people. The vectors are *Glossina palpalis* and *C. lukwinda*; the trypanosome is *T. gambiense* which gives rise to three categories of disease: mild and scanty blood infection, moderately virulent, invading the nervous system in 6-12 months, severe (like the Rhodesian form) but only feebly transmissible. These have been described before by LEISTNER.

In Nigeria and other West African countries, sleeping sickness was considered to be quiescent and sporadic before 1925, but about that time there occurred a great increase in incidence, which was due not to the spread of tsetse but to dispersal and free movement of the population. Survey teams were organized in 1930 and in the first five years found an incidence of 13.6 per cent. in 1½ million persons examined. In some places the rate was up to 20 per cent. In the next five years the extent of the infected areas was more clearly defined, and the average incidence was 8.6 per cent. In the last period—of 6 years—the incidence in new surveys was 1.5 per cent.

McLitchie stresses the point made by several authors, that even in areas in which the type of sleeping sickness is apparently mild, and in which the infected persons appear to be in good health, the death rate is high. The mild disease may be only slowly progressive as regards involvement of the nervous system, but sudden breakdown with high fever and tachycardia occurs and is apparently relatively common. The trypanosome of low virulence is specially associated with epidemics, being easily transmissible. On the other hand, true mild cases do occur in which infection persists for years, the patient and the parasite being in a state of equilibrium.

Treatment varies according to conditions, but a combination of antypol (0.5 gm.) and trypanamide (1.5 gm.) is becoming more common. This combination is given at intervals of 5 days for 8-20 injections according to severity. Pentamidine (intramuscularly) can replace antypol, and can be given at the same time as trypanamide. One intensive course, for use in small remote groups, consists of pentamidine isethionate 100 mgm. the first day followed by 200 mgm. daily to the seventh day, together with trypanamide injections to a total of 8-9 gm. in the same seven days or in ten days. Pentamidine is also used as a prophylactic.

In control, the first step has been mass treatment and this was essential in the face of epidemics. Since 1931 half a million patients have been treated, most during surveys and at dispensaries but over 50,000 at general medical stations. The incidence rate in populations examined, which rose to 20.5 per cent. in 1935, was in 1945 down to 1.7 in new surveys. The dispensaries are popular.

Control of tsetse comprises protective clearing, of streams (red clearing) and aggressive clearing, of large areas. Of the latter the Anchoa corridor is

conveyed mechanically by other biting flies, particularly tabanids, when the time between two successive bites is very short, there is little doubt that this occurs in herds of animals in tsetse-free areas of Africa though, as these are situated near to tsetse-infested areas, the long establishment of infection by mechanical transmission alone is difficult to prove. In countries far from Africa, however, such as Mauritius, the West Indies, Central America and South America, where no tsetse flies exist and where infection with *Trypanosoma vivax* among domestic animals has become a serious problem, it must be concluded that the disease is spread by mechanical transmission by biting flies. Other tsetse-borne pathogenic trypanosomes, imported into tsetse-free areas, have caused outbreaks of disease in animals, but the infections have not become established there.

These facts arouse interest in the question of the relationship of *T. brucei* to *T. evansi*, the latter is monomorphic and indistinguishable in appearance from the long, thin forms of *T. brucei*, but some strains of *T. evansi* show polymorphism and even posterior-nuclear forms, yet in experiments they failed to infect tsetse flies. Laboratory strains of *T. brucei*, maintained by syringe-passage, eventually become monomorphic, the long, thin forms alone persisting, and lose their power of developing in tsetse flies. It was found also that strains of *T. vivax* in tsetse-free countries (Ruanda and Martinique) could not develop in tsetse flies. It is suggested, therefore, that *T. evansi* has arisen from *T. brucei*, camels may have been infected with *T. brucei* during visits to tsetse-infested areas and on their return to the Sudan the infection was spread mechanically by tabanids, became established and was carried in caravans to Asia and elsewhere. An alternative suggestion that *T. brucei* was originally *T. evansi* cannot be excluded. [The articles in the list of references have nearly all been abstracted in this *Bulletin* from 1930 onwards.] J F Corson

HOPPE, J O & CHAPMAN, C W. Rôle of Glucose in Acute Parasitemic Death of the Rat Infected with *Trypanosoma equiperdum*. *J Parasitology* 1947, Dec, v 33, No 6, 509-16, 1 fig [19 refs]

Rats infected with *T. equiperdum* by intraperitoneal injection of 2 million trypanosomes survived 90.65 ± 34 hours. During the infection, the blood sugar decreased from a normal of 145.6 milligrammes per cent to 32.8 milligrammes per cent at the time of death. The sugar remained at the normal level for the first 48 hours, then decreased by 1 per cent per hour up to 72 hours and finally by 3 per cent per hour to the death of the animal. At the time of death, the trypanosomes numbered 1.566 million per cmm of blood. If 5 gm of glucose per kgm of body weight was administered orally every three hours, commencing shortly before the expected death of the rat, life would be prolonged on an average 18 hours, the trypanosomes reaching 3.744 million per cmm of blood. The rats at 48 hours of the infection survived doses of insulin not greater than 5 units per kgm, while normal rats survived 400 units per kgm. From the authors' observations, the conclusion is reached that hypoglycaemia is the cause of death in albino rats infected with *T. equiperdum*. C M Wenyon

CHEN, G & MCCREARY, J H. An Evaluation of Assay Methods for Arsenicals. *J Pharm & Exper Therap* 1947, Oct, v 91, No 2, 140-43, 1 fig

Chen *et al* previously described an *in vivo* and an *in vitro* method for the assay of trypanocidal activity of antimonials [this *Bulletin*, 1945, v 42, 869,

which the dog may serve as a test animal for differentiating *T. brucei* from the human trypanosomes. The behaviour of *T. brucei* in monkeys and other animals the susceptibility of *Cercopithecus* was low, the infection running a symptomatic course with spontaneous recovery. *Cercopithecus* was highly susceptible, the course of the disease being acute and fatal.

The index of transmissibility of the porcine and caprine strains of *T. brucei* by *G. palpalis* was higher than that of *T. gambiense*. It was found that passages through *Cercopithecus* considerably increased its transmissibility. Twelve flies fed on cultures maintained for 6 months became infected and were able to transmit the infection cyclically to guinea-pigs.

Since a chronic infection correlated with a high degree of transmissibility was an ideal condition for the maintenance of endemicity, it is thought that in the region under consideration, where game is scarce, the best reservoir host of *T. brucei* is provided by the pig.

Treatment with various drugs showed that *T. brucei* was fairly resistant to trypanamide about 0.3 gm. per kgm. being required to effect a cure in guinea-pigs. As regards tartar emetic 3 injections of 0.05 gm. was the curative dose for dogs while guinea-pigs required 1 mgm. per kgm. combined with 0.015 gm. per kgm. of Bayer 205. The latter drug produced the best results in doses of 0.05 gm. per kgm. against all three strains. On the other hand, Surfen C was ineffective.

Normal human serum had a pronounced trypanocidal action on all three strains. 1 *T. brucei* 3-6 cc. causing the disappearance of the trypanosomes from the blood in guinea-pigs, while 1 cc. had a prophylactic effect. This trypanosome was made serum-resistant by administering progressively increasing subcutaneous doses, until resistance to 100 cc. was produced in guinea-pigs.

The pathogenicity of *T. brucei* to man was tested by cyclical transmission to seven volunteers of the canine and caprine strains, from the natural hosts, after passages through domestic animals, and after rendering the trypanosomes resistant to human serum. All these attempts, except one failed. In the positive case trypanosomes were seen in a thick blood film of the volunteer three weeks after the infective bites by tsetse, but subsequent examinations of the blood and cultures were negative and inoculation of the blood to other animals produced no infection.

The human experiments were designed to elucidate the role of *T. brucei* in the genesis of acute cases of sleeping sickness of the holozerous type which occur in *gambiense* areas in the presence of *G. palpalis* vectors. The single positive case represents a transient infection in a person who was exceptionally susceptible to the infection. The authors suggest that among numerous persons exposed to the bites of tsetse-flies infected with *T. brucei* the susceptibility of some individuals might occasionally be still greater, the infection lasting long enough to allow the flies to feed, acquire an infection and transmit it further. In this way there might be produced a mutant strain of *T. brucei* which would adapt itself to the new host.

The existence of cross-immunity between *T. brucei* and *T. gambiense* points to the presence of group antigens in the polymorphic trypanosomes. It is suggested that the relationship between these trypanosomes could be tested by attempting to transform *T. gambiense* into *T. brucei* resistant to dogs or goats.

C. A. Hume

HUARE, C. A. Tsetse-borne Trypanosomiasis outside their Natural Boundaries. *Laboratoire J. Rudhart (Soc. Belg. Méd. Trop. Bruxelles)* 1947 Dec. 267-77. 28 refs.

It has been shown experimentally that pathogenic trypanosomes of man and animals in Africa which are cyclically transmitted by tsetse flies can also be

conveyed mechanically by other biting flies, particularly tabanids, when the time between two successive bites is very short, there is little doubt that this occurs in herds of animals in tsetse-free areas of Africa though, as these are situated near to tsetse-infested areas, the long establishment of infection by mechanical transmission alone is difficult to prove. In countries far from Africa, however, such as Mauritius, the West Indies, Central America and South America, where no tsetse flies exist and where infection with *Trypanosoma vivax* among domestic animals has become a serious problem, it must be concluded that the disease is spread by mechanical transmission by biting flies. Other tsetse-borne pathogenic trypanosomes, imported into tsetse-free areas, have caused outbreaks of disease in animals, but the infections have not become established there.

These facts arouse interest in the question of the relationship of *T. brucei* to *T. evansi*, the latter is monomorphic and indistinguishable in appearance from the long, thin forms of *T. brucei*, but some strains of *T. evansi* show polymorphism and even posterior-nuclear forms, yet in experiments they failed to infect tsetse flies. Laboratory strains of *T. brucei*, maintained by syringe-passage, eventually become monomorphic, the long, thin forms alone persisting, and lose their power of developing in tsetse flies. It was found also that strains of *T. vivax* in tsetse-free countries (Ruanda and Martinique) could not develop in tsetse flies. It is suggested, therefore, that *T. evansi* has arisen from *T. brucei*, camels may have been infected with *T. brucei* during visits to tsetse-infested areas and on their return to the Sudan the infection was spread mechanically by tabanids, became established and was carried in caravans to Asia and elsewhere. An alternative suggestion that *T. brucei* was originally *T. evansi* cannot be excluded. [The articles in the list of references have nearly all been abstracted in this *Bulletin* from 1930 onwards] J F Corson

HOPPE, J O & CHAPMAN, C W Rôle of Glucose in Acute Parasitemic Death of the Rat Infected with *Trypanosoma equiperdum* *J Parasitology* 1947, Dec, v 33, No 6, 509-16, 1 fig [19 refs]

Rats infected with *T. equiperdum* by intraperitoneal injection of 2 million trypanosomes survived 90 65+34 hours. During the infection, the blood sugar decreased from a normal of 145.6 milligrammes per cent to 32.8 milligrammes per cent at the time of death. The sugar remained at the normal level for the first 48 hours, then decreased by 1 per cent per hour up to 72 hours and finally by 3 per cent per hour to the death of the animal. At the time of death, the trypanosomes numbered 1 566 million per cmm of blood. If 5 gm of glucose per kgm of body weight was administered orally every three hours, commencing shortly before the expected death of the rat, life would be prolonged on an average 18 hours, the trypanosomes reaching 3 744 million per cmm of blood. The rats at 48 hours of the infection survived doses of insulin not greater than 5 units per kgm, while normal rats survived 400 units per kgm. From the authors' observations, the conclusion is reached that hypoglycaemia is the cause of death in albino rats infected with *T. equiperdum*. C M Wenyon

CHEN, G & MCCREARY, J H An Evaluation of Assay Methods for Arsenicals *J Pharm & Exper Therap* 1947, Oct, v 91, No 2, 140-43, 1 fig

Chen *et al* previously described an *in vivo* and an *in vitro* method for the assay of trypanocidal activity of antimonials [this *Bulletin*, 1945, v 42, 869, (320)]

1946, v. 43 315]. The former was based on the suppressive and curative activity of the drugs in *T. evansi* infections of mice and the latter on the interference with glucose metabolism of the isolated trypanosomes. Similar methods have now been used for evaluating arsenicals. In addition, the concentration of various drugs which caused death of the trypanosomes over an observation period of one hour was determined in coverslip preparations of infected blood mixed with Ringer Locke solution. The results obtained by the two *in vivo* methods agreed well among themselves and also with those based on interference with glucose metabolism in the case of trivalent compounds. When potencies were estimated by comparing lethal concentrations of the substances in coverslip preparations, the results were not in harmony with those of the other tests. The authors consider that the suppressive method of estimating trypanocidal potencies of arsenicals is satisfactory. The *in vivo* method, based on interference with glucose metabolism by the trypanosomes, has advantages for certain classes of arsenicals on account of its simplicity.

FLOCH H. La maladie de Chagas en Guyane française [Chagas's Disease in French Guiana.] Institut Pasteur de la Guyane et du Territoire de l'Inim. Publication No. 164 1947 Nov. 5 pp. [13 refs.]

FLOCH H. & CAMAIN R. Deux nouveaux cas de maladie de Chagas. Guyane française [Two New Cases of Chagas's Disease in French Guiana.] Institut Pasteur de la Guyane et du Territoire de l'Inim. Publication No. 162. 1947 Sept. 4 pp.

PELLEGRINO J. & MESQUITA, S. S. A reação de fixação do complemento na doença de Chagas. I.—Nota sobre falsas reações positivas e dúvidas feitas com antígeno de cultura de "Schizotrypanum cruzi" em soro conservados em geladeira. [Complement Fixation in Chagas's Disease. I. False and Doubtful Positives with Culture Antigen.] *Brasil-Médica*. 1947 Nov. 22 & 29. 61 Nov. 47 48, 398-401 [13 refs.] English summary.

Diagnosis of Chagas's disease in the early stages, when *T. cruzi* is abundant in the blood-stream, is a simple matter; later we have to rely more on xenodiagnosis, inoculation and cultivation. Such methods, especially xenodiagnosis, are lengthy and not always certain. Hence the value of the Guerreiro-Machado reaction in these stages with suspensions of trypanosomes from the blood of infected animals (see this Bulletin 1928, v. 3 358 1938, v. 25 771). The authors in this study have used a culture of *T. cruzi* prepared by Davis's method [ibid. 1943, v. 40 880 slightly modified by Metz and FREITA (ibid. 1945 v. 4, 973 1947, 44 571). They found that sera of some persons, apparently in good health with no signs of infection, gave doubtful and even in some (though not many) cases positive complement fixation if the sera had been kept in an ice-chest even with addition of merthiolate. To avoid this error the reaction must be carried out with freshly obtained serum. The results are shown in protocols.

LEISHMANIASIS

HAWKING F. Growth of Protozoa in Tissue Culture. V. *Leishmania donovani*. *J. Nat. Res. Soc. Trop. Med. & Hyg.* 1948 Jan. v. 41 No. 4 545-54. 23 figs. (2 coloured). 15 refs.

The author has succeeded in cultivating *Leishmania donovani* in tissue culture employing hamster spleen as the tissue and rabbit serum in the liquid portion

Leishmaniasis

Vol. 45, No 6]

in place of hamster serum. In cultures made from infected spleens, active multiplication of parasites occurred and these were able to invade uninfected spleen growing in the same Carrell flask. In most of the cultures maintained for more than sixteen days the parasites escaped from the cells and formed masses of flagellates which grew and multiplied at 37°C. Cultures of flagellates growing at 25°C were added to culture of hamster spleen growing at 37°C, while some of the flagellates entered cells and appeared as leishmania forms, while other flagellates multiplied in the fluid part of the medium. AVERSA, T & CROSCA, A. Modificazioni del quadro ematologico e del mielogramma sotto l'influenza della terapia abbinata di ferro e di antimonio nella leishmaniosi interna infantile. [Changes in the Blood Picture and the Myelogram as a Result of Combined Iron and Antimony Treatment in Infantile Kala Azar] *Pediatrics* 1947, v 55, Nos 10/12, 607-21

The English summary appended to the paper is as follows —
 "The authors have studied the changes of the blood-picture and myelogram under the influence of combined iron- and antimony therapy, in 9 children affected by visceral leishmaniasis

"The improvement of the blood-picture was neither more rapid nor more accentuated than that we generally observe in children treated only with antimony

"Likewise the medullary alterations were not differently modified"

BURGIO, G R. Rilevi statistico-clinici sull'endemia del kala-azar nostrano nella Sicilia occidentale negli anni 1939-1945. [Infantile Kala Azar in Western Sicily] *Pediatrics* 1947, v 55, Nos 1/3, 53-80, 9 graphs & 1 map [30 refs] English summary

Basing his observations on children in Palermo seen at the pediatric clinic, in the children's hospital or attending its out-patient department, the author finds that the cases of kala azar have remained fairly constant, the numbers for 1939 to 1943 being 26, 27, 26, 33, 18. In 1944 and 1945 however, there was a marked increase, the figures 80 and 84 being obtained. This increase was due largely to the cases from the Palermo district. C M Wenyon

CARNEVALE, A. La velocità di diffusione di un elettrolita (HCl), nel gel-serico, nella leishmaniosi interna. [Diffusion Speed of an Electrolyte in Frozen Kala Azar Serum] *Pediatrics* 1947, v 55, Nos 1/3, 81-6 English summary (7 lines)

The author has found that an electrolyte (HCl) diffused more rapidly in serum gel of 14 of 15 cases of infantile kala azar (the normal rate being 44-47 mm in 24 hours). This increase to 48-51 mm appears to be related to the alteration which occurs in the albumin/globulin relationship, the globulin being increased in kala azar. In 7 healthy children, a rate of 45 or 46 was obtained. The technique, which consists essentially of gelification of the serum with propionic acid and then adding a layer of HCl and observing penetration of the latter by colour change in Congo red previously incorporated is described. GUIMARÃES, F. A. Visceralização da "Leishmania brasiliensis" Vianna, 1911 em hamsters ("Cricetus auratus") (Nota preliminar) [Visceral *L. brasiliensis* Infection in Hamsters (*Cricetus cricetus* = *C. auratus*)] *Brasil-Médico* 1947 Nov. 22 & 29 v. 61 Nos. 47/48 365-6 2 figs. Dec. 29 & 27 Nos. 51/52, 439 (Erratum).

With material taken from a sore containing leishmaniasis, the author inoculated a hamster on the nose and in the peri-ocular region. Seven months later the animal was examined. There were no cutaneous lesions, but there was a generalized leishmaniasis infection which is illustrated by photographs of a section of the spleen and a smear of the bone marrow. This appears to be the first record of a generalized infection with *Leishmania brasiliensis*. Similar infections have been produced by a number of observers with *Leishmania tropica*. In the second note the name of the hamster is corrected to *Cricetus auratus* from *Cricetus cricetus*. C. M. Wrayton

FULTON, J. D. The Constitution of Photostilbamidine, the Irradiation Product of Stilbamidine. *Brit. J. Pharmacol.* 1948, Mar., v. 3 No. 1 75-9 2 figs. [10 refs.]

"Irradiation of a solution of trans-stilbamidine in sunlight gave a substance which on hydrolysis to the corresponding acid, followed by decarboxylation, yielded a hydrocarbon m.p. 163° identical with that obtained by irradiation of stilbene. The hydrocarbon previously described as di-stilbene has now been shown by x-ray crystallographic analysis to be 1,2,3,4-tetraphenylcyclobutane containing a centre of symmetry. A second isomeric hydrocarbon m.p. 149° was also obtained in the same series of reactions, but its molecular configuration has not yet been determined. The isolation of these two hydrocarbons is in agreement with the view that stilbamidine undergoes dimerization on irradiation of its solutions. [See this *Bulletin* 1947 v. 44 988.]

FEVERS OF THE TYPHUS GROUP

JADIN, J. & D'HOOGHE, M. La fièvre rouge congolaise peut être aussi du typhus historique. Cases of Historic Typhus also may be included under the Name Red Fever of the Congo. *Liber Jubilare J. Kadish* (Soc. Belge Méd. T. p. Brussels) 1947 Dec., 279-90 2 charts. [10 refs.]

Jadin has already isolated strains of murine-typhus rickettsiae from patients regarded as suffering from the red fever of the Congo. See this *Bulletin*, 1948, v. 45 325.

The authors now claim to have isolated strains of epidemic typhus rickettsiae from three out of eight patients in whose cases the same diagnosis was made.

The features said to be characteristic of the disease are fever, headache, rash, and a Weil-Felix reaction of the *Proteus* O1K type.

Six of the eight patients whose cases are described in the present paper reacted with Pr O1K at titres of 1:200 or over (three also reacted with Pr O1A at 1:100 or 1:200) and another with Pr O1A at 1:200.

[There seems to be no valid reason for retaining the name *fièvre rouge congolaise* for fevers shown to belong to the typhus group.]

GREIFF, D & PINKERTON, H **Effect of Enzyme Inhibitors and Activators on the Multiplication of Typhus Rickettsiae** III Correlation of Effects of PABA and KCN with Oxygen Consumption in Embryonate Eggs J Exper Med 1948, Mar 1, v 87, No 3, 175-97, 2 figs [28 refs]

This paper is the third of a series by the same authors [See this Bulletin, 1945, v 42, 362, and 1946, v 43, 22]
Using a special technique, which is described in the paper, the authors found that the rate of uptake of oxygen by eggs containing developing chick embryos became slightly increased on the fourth day after inoculation with rickettsiae and then fell rapidly during the later days

PABA (para-aminobenzoic acid) introduced as described in the earlier papers caused a pronounced increase in the oxygen intake of the infected eggs, whereas MABA (meta-aminobenzoic acid) and OABA (ortho-aminobenzoic acid) caused a moderate degree of depression in the intake
The small doses of potassium cyanide which had been found to enhance rickettsial growth, caused a striking depression in the oxygen intake
These experiments are regarded as supporting the hypothesis that rickettsial growth is inversely proportional to the respiratory rate of the host cells
Although PABA forms part of the folic-acid molecule, the latter drug in tolerated doses did not increase the oxygen uptake and had no rickettsiostatic action

LOEBNER, R J, JELLISON, W L, BECK, M D, PARKER, R R & SHEPARD C C **Q Fever Studies in Southern California I Recovery of Rickettsia burnetii from Raw Milk** Pub Health Rep Wash 1948, Feb 13, v 63, No 7, 214-22

The circumstances leading up to the present investigations are stated to have been that studies not yet published had indicated (1) that 117 cases of Q fever had occurred in South California during 1947, (2) that more than half the patients had been workers in dairies or residents in places close to dairies, and (3) that 10-20 per cent of the dairy cows of the Los Angeles area had given positive complement-fixation reactions with Q fever antigen
The authors give details of the very thorough investigations carried out by them at the U S A National Institute of Health, the Q Fever Laboratory, and

Rocky Mountain Laboratory, at all three of which similar results were obtained from the examination of the same samples of milk. Fifty samples of milk were obtained from four dairies, in association with which cases of Q fever had occurred. Most of the samples consisted of pools of milk each of which was obtained from 25-30 cows but a few were from individual cows. Each sample was tested by guinea-pig inoculation, and from 40 of them evidence of Q fever infection was obtained in the form of complement fixation reactions against Q fever antigens. Most of the reacting guinea-pigs had febrile reactions, and from eight of these, which were sacrificed, strains of *Rickettsia burnetii* were isolated by further guinea-pig inoculation and by yolk-sac culture.

Each of several strains that were tested for cross immunity against known strains of *R. burnetii* gave positive results.

None of the infected cows showed any signs of illness or of diminution in the yield of milk. The available evidence did not suggest that infection was transmitted to human beings by drinking milk, though it was considered possible that milk might be a source of infection by some mode yet to be determined.

YELLOW FEVER

WADDELL, Mary B. & TAYLOR, R. M. Studies on Cyclical Passage of Yellow Fever Virus in South American Mammals and Mosquitoes. IV. Marsupials (*Metachirus nudicaudatus* and *Marmosa murina*) in combination with *Aedes aegypti* as Vector. *Amer. J. Trop. Med.* 1948, Jan., v 28, No. 1: 87-100, 3 figs. [14 refs.]

The authors have found that under appropriate conditions in the laboratory certain strains of jungle yellow fever virus may be maintained in cyclical passages through marsupials (*Metachirus nudicaudatus* and *Marmosa murina*) in combination with *Aedes aegypti* as the insect vector and that strain differences of the virus may be of such magnitude as to affect their cyclical passage in *Metachirus*. These strain differences, at least in so far as the host-vector cycles are concerned, are influenced by the nature of the host and possibly of the vector through which recent passages have occurred.

These marsupials, when they are infected, do not so readily or so consistently infect normal mosquitoes as do two species of marmosets which have been studied.

The results of these laboratory experiments suggest that *Metachirus nudicaudatus* and *Marmosa murina* can under favourable circumstances, serve as vertebrate hosts in the maintenance of certain strains of jungle yellow fever but before they are incriminated as natural hosts of the virus, supporting epidemiological evidence is required. In a rather comprehensive field study in a region where the disease is endemic in the forests, no information was obtained which implied that marsupials played a significant rôle in the propagation of the virus [see this Bulletin 1947, 44: 414].

F. O. MacCallum

HUGHES, T. P. & PERLOWAGORA, Akma. The Reaction of certain Species of Bats to Yellow Fever Virus. *Amer. J. Trop. Med.* 1948, Jan. v 28, No. 1: 101-3.

The possibility that yellow fever virus may be disseminated between isolated forest patches through transport by flying vertebrates has been suggested frequently but has been subjected to little experimental test. HUGHES (see this Bulletin, 1933, v 30) failed to find virus in the blood stream of bats taken by

Aedes aegypti infected with either of two strains of yellow fever virus. More recently, LAEMMERT *et al* [see this *Bulletin*, 1947, v 44, 414] found that only one of 81 bat sera from an area of endemic yellow fever infection neutralized the virus, and they considered this one result non-specific.

Hughes and Perlowagora carried out a total of 254 tests for the presence of virus in the sera of bats which had been exposed to it, either by injection or by mosquito bite, but no virus was detected. Neither did any of the 55 bats which were tested develop neutralizing antibodies as a result of this exposure. They used *Eumops californicus*, *Phyllostomus panamensis* and *Molossus* sp. which frequent forest areas.

These results indicate that tests on sera of captured wild bats can give no information as to whether these vertebrates have previously been in contact with yellow fever virus.

F O MacCallum

FOX, J P, DA CUNHA, J F & KOSSOBUDZKI, S L. Additional Observations on the Duration of Humoral Immunity following Vaccination with the 17D Strain of Yellow Fever Virus. *Amer J Hyg* 1948, Jan, v 47, No 1, 64-70.

This is a report of examination of sera of several vaccinated groups in whom immunity has been followed for several years.

Though there has been some diminution in the percentage of individuals with strong protection in the mouse protection test, 4 to 6 years after inoculation practically all sera still contained detectable antibody. As in a previous study by FOX & CABRAL [this *Bulletin*, 1943, v 40, 451], there was a suggestion of short duration of immunity in children, but the difference between results in children and older persons was not statistically significant.

These results, together with those of SMITHBURN and MAHAFFY in Uganda [see this *Bulletin*, 1946, v 43, 34] and BUGHER and GAST-GALVIS in Colombia [*ibid*, 1944, v 41, 478] give complete support for the four-year certificate of immunity to yellow fever which is in current use.

FROES H P. Proyecto de campaña continental para la erradicación del *Aedes aegypti*. [Scheme for a Pan-American Campaign towards the Eradication of *Aedes aegypti*.] *Bol Oficina Sanitaria Panamericana* 1947 Oct v 26, No 10 842-51. English summary.

See also p 485, GIGLIOLI, An Investigation of the House-frequenting Habits of Mosquitoes of the British Guiana Coastland in relation to the Use of DDT.

DE CAIRES, P F. *Aedes aegypti* Control in the absence of a Piped Potable Water Supply. *Amer J Trop Med* 1947, Nov, v 27, No 6, 733-43, 12 figs.

The classical *Aedes aegypti* control measures, as established in Brazil by the International Health Division of the Rockefeller Foundation, were employed in British Guiana during the recent war years, the Colony having a vitally important source of supply of bauxite. Briefly, these measures amounted to a system of careful inspection of waters for larvae of *Aedes aegypti*, this involved the provision of staff for inspection of water containers in and around dwellings, in dock-areas and shipping, and of water collections difficult of access, lastly other persons were trained for adult mosquito catching. *Aedes aegypti* house indices (the percentage of houses inspected in which adult mosquitoes or water receptacles containing pupae, larvae or eggs were found) became low, but fluctuated with rainfall, and eradication was not achieved in urban areas. Persistence of breeding was contributed to by a 4-day egg-to-adult cycle which occurred at times. It was not practical nor economical to increase the inspection rate from a 7-day to a 4-day interval.

Georgetown (8° N 58° W) with a population of 80,000 has no piped potable water supply and in consequence rainwater is collected from the roofs by galvanized roof gutters and the water is led into large storage containers such as vats, tanks, barrels and drums. The variety of breeding places, and the methods of inspection and control, are adequately described and illustrated. The necessity for strict discipline of inspection squads is stressed: the process of constant checking of the work of inspectors, of discovering their inefficiencies, and bringing them to book, is unpleasant but essential.

The human factor of inefficiency in inspection is eliminated by the introduction of DDT applied on one occasion as a residual insecticide to the interior walls of all houses. Hidden foci of breeding are no longer a source of trouble. A five per cent. solution of DDT in kerosene is applied at an estimated dosage of 100 mgm. DDT per square foot of wall and ceiling. The cost for a 3 to 5-roomed house is about 1.6 dollars which represents 0.47 to 0.59 dollars (British West Indies) per head of population. The overall cost is much cheaper than the cost of the classical inspection service. In rural areas, the classical method could produce a zero index in four months at a cost of 1.39 dollars per head of population, urban costs being infinitely greater.

The Georgetown *Aedes aegypti* house index, which under classical control methods fluctuated between 1 and 3 per cent. fell to zero within 12 months of the introduction of the use of DDT as a residual insecticide. In the event of *Aedes* re-establishing breeding in an area, it is believed that a single localized re-application of DDT will be effective in eradicating the focus within a few weeks.

DENGUE AND ALLIED FEVERS

FLORIO L. & MILLER, Mabel S. Epidemiology of Colorado Tick Fever (mos.)
Pub. Health 1948, Feb., v. 38 No. 2, 711-13.

The presence of the virus of Colorado tick fever was demonstrated by hamster inoculation in nine out of ten pools of ticks (*Dermacentor andersoni*) collected from areas in Denver where the disease is endemic.

In a study of experimental infection among ticks it was found that hamsters could be infected by the bites of larvae whose parents had been infected by biting infected hamsters. By inoculation experiments it was shown that larvae, nymphs and adults belonging to the same brood of infected ticks were infective to hamsters, though the eggs of these broods were not infective.

Larval ticks fed on infected hamsters remained infective after reaching the nymphal and adult stages.

Dog ticks (*Dermacentor variabilis*) collected in Long Island, where the disease is not known to occur, were found to be infected with a virus similar to, or identical with, the virus of Colorado tick fever.

PLAGUE

TIEN T. H., LANDAUER E., MIYAGAWA F., KOBAYASHI, G. & OKAWA U. G.
Primary Pneumonic Plague in Mukden, 1946, and Report of 29 Cases. *Chin. J. Recovers.* J. J. Ch. Dis. 1948 Jan Feb 62, No. 1 52-53 3 figs. (20 refs.)

Primary pneumonic plague in Manchuria is not a new occurrence for there were the epidemics of 1910 and 1920. What is new for this very fatal and

Plague

Vol 45, No 6]

infective type of plague is the report of three recoveries. Although these cases occurred towards the end of the epidemic the circumstances point to the use of sulphadiazine as "the principal factor in the recovery" of three out of five patients treated. The authors believe that the infection was started by a carrier who came into Mukden during the incubation period and died after a very short illness. Contacts of proven cases of primary plague were quarantined, they numbered 67, and 23 of these developed plague. An interesting point is emphasized that, out of 42 individuals without symptoms, who had throat swabbings made daily, 4 were found to harbour virulent *P. pestis* and that this infection persisted for 6 to 15 days. "At least one of the 4 is believed to have been a true healthy carrier."

W F Harvey

PUBLIC HEALTH REP Wash 1948, Feb 20, v 63, No 8, 243 Plague
Infection in Dawson County, Texas

As a result of evidence of plague in native rodents in Cochran County and in Dawson County, Texas in 1946 and 1947, respectively, the Texas State Dept of Health, in co-operation with the U S Public Health Service, surveyed the ecology of the reservoirs and vectors of plague in the affected counties.

At the end of 1947 it was reported, as a result of these studies, that plague infection had been found again in Dawson County, eight miles west of Lamesa. The infection was detected in a pool of 141 fleas from 14 pack rats (*Neotoma micropus*)

H J O'D Burke-Gaffney

ARAÚJO COSTA, Gobert Contribuição ao diagnóstico da peste nos ratos.
[Diagnosis of Plague in Rats] Monografias do Serviço Nacional de Peste I
Rio de Janeiro, Brasil 250 pp [Bibliography]

A monograph of 250 pages restricted to the diagnosis of plague in rats might be doubtfully regarded as a real work of reference. It may be stated, therefore, at the outset that the abundant information contained in it, after a full historical introduction of 50 pages, relates as much to bacteriology as to zoology. A full summary indicates how much is the author's own personal experience infected with plague, in Rio de Janeiro, and how much is a penetrating analysis and test of claims made by other authors. A short set of conclusions is, itself, a summary, and the bibliography extends to 334 references, each of which is presented under full explanatory title. There are no illustrations and no graphs, but there are many full tables which are in many respects more useful than graphic presentations. We have now for some time been accustomed to very thorough deliverances on plague from America and owe a great deal of our knowledge of epizootic and enzootic plague to these. One might even, protestingly and without seriousness, speak of America as the "home" of plague, a mere counterblast to the description of India as the "home" of cholera. The fact that this work is written in Portuguese should not be a deterrent to its use by anyone who is well versed in the subject matter, for it is easy to read and is packed with information.

Some of the facts, or, as the case may be, conclusions, can be shortly set out — The rats reached the laboratory in a varied condition, some 1,500 still alive, some recently dead and many in an advanced state of decomposition. Necropsies were undertaken in those of the species *R. norvegicus*, *R. alexandrinus*, *R. rattus* and *M. musculus*. Fleas on these rodents belonged in greatest number, 593 out of 598, to the species *X. brasiliensis* and *X. cheopis*. Special attention was paid to the possibility of organismal non-plague infections, contaminating and epizootic, which can lead the field worker astray in the

diagnosis of plague. Even *Trypanosoma lewisi* came in for attention, as might diseases like tularemia and melioidosis. Contaminating organisms of sub-aerogenes, *Proteus* and *Salmonella* groups often give trouble morphologically. It is evident that the author separates the pasteurillas of the animal haemorrhagic septicaemias, which seem to be one for every animal (or *S. typhi* and *S. dysenteriae* *subsp. dysenteriae* *gallinae* etc.) from *Pasteurella pestis*. The chief differentiation, however that is obligatory in the rat is that of *P. pestis* from *P. pseudotuberculosis rodentium* and this receives full consideration.

Four methods are singled out for a presumptive test and these are designated, the classical method, the method of thermoprecipitation that of bone marrow puncture and the flea examination. Full identification is supplementary to the presumptive test. The author maintains strongly the value of bone marrow examination in decomposed animals. A great many suggested culture media have been examined for their selective differentiation value and the characters of the plague bacillus which are stressed are morphology motility at 22°C (Levinthal's method) fermentation of glucose lactose and saccharose the indole methyl red and reductase tests and finally an inoculation that is to say guinea pig test. Much valuable direction is given to the type of plague, acute and chronic, especially in the declining epizootic which may justly bear such names as mitigated benign, resolving, residual and inapparent plague.

An index would add greatly to the value of this monograph as a reference work.

[It is rather surprising that in a great many extensive bibliographies, as this one is, there should be no reference to the Royal Indian Commission (1904-09) although we find references to German, Austrian, English and even Australian Commissions. In historical texts and in text books, too the "Existence of an Endemic Focus of Plague in the Foothills of the Himalayas" is very little noticed although it was given a chapter in the Commission Report referred to, and by HAXKIN (*Ann. Inst. Pasteur* 1898, v. 12, 711). It existed before the arrival of plague at Bombay from Hong Kong and was said to be commonly preceded by a rat epizootic. Another constant omission which is understandable considering the local character of the publications, is reference to the basic investigations of Glen Liston on rat flea transmission of plague and to Ashburnton Thomson's Report on the Second Outbreak of Plague in Sydney 1902. They formed very important supplements to the work of Semond in Bombay and were milestones on our path of knowledge. Liston's first study of "Plague Rats and Fleas" and the part the latter played in the transfer of plague from rats to man was communicated to the Bombay Medical and Physical Society in February 1903 and a second to the Bombay Natural History Society in April 1903.]

SMITH W. E. & PIERCE R. B. Reducing the Pyrogenicity of Concentrated Protein Solutions. *J. Bacteriol.* 1947 Dec 54 No. 8 715-18.

The pyrogenicity of concentrated protein solutions can often be reduced by treatment with decalco and by filtration through 5-6 pads of the Republic series.

The amount of decalco and the area of pad space used are functions of the degree of pyrogenicity and of the protein concentration of the solution, and for maximum effect these should be determined for each solution to be

examined In practice, for 6 to 8 per cent protein solutions of mild pyrogenicity, 30 g of 'decalso' and 40 sq inches of pad surface per liter of solution have given adequate reduction of pyrogenicity"

PASRICHA, C L, PAUL, B M, DAS GUPTA, A C & DAS, A K Sulphadiazine in the Treatment of Cholera. *Indian Med Gaz* 1947, Sept, v 82, No 9, 518

"A series of 425 cholera patients were treated with sulphadiazine in addition to the usual saline supportive treatment The death rate in this series was 8.2 per cent A parallel series of 423 control cases not treated with sulphadiazine gave a death rate of 9.5 per cent

"Another series of 451 cases treated with sulphadiazine was compared with a parallel series of 463 cases treated with sulphaguanidine The mortality in the sulphadiazine series was 7.9 per cent whereas in the sulphaguanidine series it was 4.3 per cent

"Sulphadiazine in the dosage used had no beneficial effect on cholera"

PASRICHA, C L, PAUL, B M, DAS GUPTA, A C & DAS, A K Sulphaguanidine in the Treatment of Cholera *Indian Med Gaz* 1947, Sept, v 82, No 9, 518-20

"A series of 1,118 hospitalized cholera patients were treated with sulphaguanidine with a death rate of 3.7 per cent A parallel series of 1,170 control cases were treated in exactly the same way but not given sulphaguanidine and the death rate was 7.5 per cent A series of 60 cholera patients were treated with sulphaguanidine in village homes No supportive treatment was possible The death rate in this series was 18.3 per cent, whereas in a parallel control series of 59 cases, the death rate was 40.7 per cent

"Sulphaguanidine is thus of considerable value in the treatment of cholera"

SEAL, S C Sulphaguanidine in the Treatment of Cholera under Rural Conditions. (A Report on 290 Cases) *J Indian Med Ass* 1947, Dec, v 17, No 3, 85-90

Many reports now bear witness to the value of sulphaguanidine in the treatment of cholera in hospital patients Such patients are generally late arrivals and the treatment might be more effective still at an earlier stage of the disease The present account relates to 30 small outbreaks of cholera in 29 villages, where the treatment was carried out under actual field conditions in which both the community and the environment remained uncontrolled The total number of cases was 290, and sulphaguanidine was used in 134, with only two deaths the remainder, not alternate cases but treated otherwise, furnished 67 deaths The difference in the fatality rates is very significant, the proportion of 1.5 to 43.5 per cent, respectively No toxic symptoms could be ascribed to the sulphaguanidine, which was administered as initial dose of 3 gm followed by further doses of 3 gm every 3 hours, until stools were reduced in number to two or less per day, after which the dose became 1 gramme every 6 hours for the next 24 hours The author considers that the drug may be safely kept in villages and administered generally in suspicious gastro-intestinal diseases as an emergency or first aid measure

LOKESHAO H J & BAILER, M. E. Investigation of some Newer Sulfonamides as Intestinal Chemotherapeutic Agents. *J Pharm. & Exper Therap* 1948, Feb. v 92 No. 2, 190-208, 1 fig [23 refs.]

"Preliminary study of three new sulfonamides as intestinal chemotherapeutic agents is reported 2-sulfanilamido-5-carbamylthiazole (N-succinamylsulfanilamido) thiazole and 2 (N-succinylsulfanilamido) 1,3,4-thiadiazole

"The presence of the carbamyl group in the 5-position of sulfathiazole greatly reduces absorption from the gastro-intestinal tract and activity *in vitro*. However marked anti-coli action was demonstrated in mice and dogs. Sulfacarbamylthiazole is relatively stable and activity is apparently due to the drug *per se*.

"Replacement of the carboxy group of succinylsulfathiazole with the carbamyl group yields a compound considerably more labile than the parent drug. While absorption was slight following oral administration of succinamylsulfathiazole to mice and dogs, the drug showed but little anti-coli activity *in vivo*.

"Substitution of the succinyl radical in the N¹ position of sulfathiazole results in a compound highly active in the intestinal tract of both mice and dogs and only slightly absorbed into the blood. The anti-coli activity of succinylsulfathiazole was found to be much greater than that of sulfathiazine in mice and about equal to the latter drug in dogs. Data seem to establish succinylsulfathiazole as a potentially useful drug for trial in therapy of enteric infections.

BRATNAGAR, S S FERNANDES, F DE SA, J & DIVEKAR, P V. A New Sulpha Compound ("6257") and its Use in Human Cholera Infection. (Correspondence. *Nature* 1948, Mar 13, 305-8.

Sulphonamides have become currently used drugs in cholera. A new compound is now put forward with considerable promise of cure. It is described as a condensation product of two molecules of 2 p-amino-benzene sulphonamido-thiazole (Cibazol) and three molecules of formaldehyde with molar weight much greater than that of any other sulpha compound so far employed in clinical therapy.

In vitro experiments have shown this substance to have bacteriostatic power and, in greater concentration, powerful bactericidal action. Further experimentation *in vivo* on mice gave indication that pre-infectious administration by subcutaneous or intraperitoneal routes could protect mice against intraperitoneal injection of 2 MLD of cholera vibrios. The drug has already been tried in the field in total dosage of 23 gm. given as 10 gm. on the first day, two doses of 4 gm. on the second day and two 1 gm. each morning and evening every subsequent day for five days. Some 85 cases of biologically established cholera have undergone treatment and the mortality was only 4 per cent, presenting a marked contrast to the estimated mortality of more than 60 per cent during the past seasons. It is important to note that no toxic effect even with a maximum dose of 50 gm. were observed. The drug may also be used prophylactically. W F Harry

AMOEBIASIS AND INTESTINAL PROTOZOAL INFECTIONS

STARKEY, H & POOLE, J **Survey of Intestinal Parasites in Repatriated Prisoners of War from Hong Kong** *Canadian Med Ass J* 1947, Oct, v 57, No 4, 377-9

The authors examined the stools of 453 Canadian ex-prisoners of war from Hong Kong several months after their repatriation to Quebec and the Maritime Provinces. Normal stools were examined daily for 3 days and again on the 5th and 6th days. On the 4th day a fresh specimen was examined after purgation. Direct examination for parasites was made in saline and identification was based on stained preparation. Washed stools were examined for cysts by the standard zinc sulphate flotation method.

In 231 cases parasites were found in normal stools and in 41 they were only found after purgation. In many cases they were found in the specimens of the 5th and 6th days and not in the purge specimen itself.

Pathogenic parasites were found in 26.7 per cent of cases and non-pathogenic in 41.3 per cent. Of the former, *Giardia* and *Ascaris* accounted for some 9 per cent each, *E. histolytica* for 7 per cent and *Ancylostoma* for 4 per cent. (It is pointed out that these percentages are individual, owing to the presence of mixed infections in some cases.)

E. coli was found in 36.4 per cent, *Endolimax nana* in 22.5 and *Trichuris trichiura* in 17 per cent.

Other parasites were found in less than 3 per cent of patients. The findings are analysed in relation to a history of amoebic dysentery, of intestinal upsets, of general asthenia and of no complaints since return to Canada.

From this analysis, it is revealed that *E. histolytica* occurred in 3.6 per cent of those without histories or symptoms of acute amoebic dysentery, of those returning to Canada, in 7.5 per cent of those with a definite history, and in 9.5 per cent of those with vague symptoms.

It is pointed out that the group under survey had been examined, and where necessary treated, on their arrival in Canada.

The authors refer to the findings of MILLER (*Canadian Med Ass J* 1946 v 55, 336) who suggested that the incidence of *E. histolytica* in the general population of Canada was probably about 2 per cent. In the present survey it was about 7 per cent. The only sub-group in this survey approximating to the incidence quoted for the general population was that of men having no history of typical amoebic dysentery and no complaints since returning to Canada (3.6 per cent).

The authors conclude that in routine survey of faeces for parasites, it is desirable to include a purge in the routine, and also to examine more specimens for at least two days thereafter. They also conclude that those who were prisoners of war in the Far East carry a higher percentage of pathogenic intestinal parasites than do residents of Canada.

ANDERSON, H H & HANSEN, E L **Cultivation of *Endameba histolytica* Libér**
Jubilaris J Rodhain (Soc Belge Méd Trop, Brussels) 1947, Dec, 47-61, 2 figs [43 refs]

The authors trace the development of media for the cultivation of *E. histolytica* since BOECK and DRBHOLAV's success in 1925. They finally describe a new medium containing only synthetic products. There are 12 amino-acids, nucleic acid, rice powder, cholesterol, 11 vitamins and various salts. In it, with only a single bacillus "t", over 170 compounds have been tested for their

amoebicidal activity. Contrary to expectation, based on LAIDLAW's findings with emetine various agents were not uniformly more active in the liquid medium. The activity of the arsenoxides was lower in the liquid medium than in that with a solid base. With most other chemical types only insignificant differences were noted. It is hoped that a medium containing only synthetic ingredients may afford an understanding of the growth requirements of *E. histolytica*.

C. M. Wray.

DOBELL, C. An Improved Method for testing the Action of Emetine and other Chemicals on *Entamoeba histolytica* in Cultures. *Labor. Julius J. Rothstein* (Soc. Belg. Méd. Trop. Brussels). 1947 Dec., 201-11 (15 refs.)

By the use of a liquid medium consisting of dilute horse-serum (1-8 Ringier's fluid) with rice starch and 0.2 per cent. disodium hydrogen phosphate as buffer cultures of *E. histolytica* have been obtained and used for testing the action of emetine. This medium, first described by LAIDLAW, DOBELL and BISSON in 1928 has been employed by Dobell since then. The amoebic culture has been purified so that *E. histolytica* with the single organism *Bact. coli* have been obtained. In order to ensure that the amoebae grow in subculture the medium is inoculated with the bacillus and incubated for 24 hours before the amoebic subculture is made into it. In this way it has been shown that emetine in a strength of 1-5,000,000 is invariably fatal to *E. histolytica* within 4 days and that they sometimes succumb to dilutions of 1-20,000,000. The author thinks that by following the technique described in the paper there is an opportunity of testing the action of other substances which are calculated to cure amoebic dysentery.

C. M. Wray.

SIGUIER, F. SARRAZIN, A. & PÉRIER, R. Typhlo-hépatite amibienne récurrente à court terme évoluant depuis deux ans chez une coloniale transplantée. [Amoebic Typhlo-Hepatitis with Frequent Relapses at Short Intervals during Two Years.] *Bull. et Mém. Soc. Méd. Hôp. de Paris*. 1948, Vol. 1/2, 27-30.

The authors describe a condition they refer to as an amoebic typhlo-hepatitis with frequent relapses at short intervals. The symptoms and signs are inconclusive but there is infiltration of the caeco-colic region in association with hepatic pain and discomfort and prostration. This liver trouble recurs at short intervals—in some cases it resolves spontaneously—in others it responds to emetine, and in yet others it is resistant to emetine.

They describe in detail such a case of suspected liver involvement without any evidence of frank abscess—this was treated for over two years on each recurrence with emetine with temporary benefit. The patient in due course showed evidence of emetine poisoning and she finally absconded. 1 R D 44ms

ACLESAN, H. J. P. & GORDON, H. Hepatic Amoebiasis. *U.S. Nav. Med. Bull.* 1948, Jan. Feb. v. 48 No. 1 22-39 10 figs. 14 refs.

In the sense of this paper the term hepatic amoebiasis covers amoebic hepatitis and amoebic abscess of the liver. The three possible routes of invasion by the amoeba are discussed: (1) Direct extension through the bowel wall, peritoneal cavity and capsule of the liver. (2) Extension by the lymphatic route. (3) Extension from the bowel through tributaries of the portal vein, generally considered to be the most common method.

Hepatic amoebiasis is suggested in cases which fail to respond to penicillin therapy with or without sulphonamide and which present signs pointing to

acute liver disease, with or without jaundice, and accompanied by leucocytosis, chills and fever. The elimination of intestinal amoebic infection forms an important part in the treatment of hepatic amoebiasis. In the six cases detailed in this report, open operation and aspiration were avoided. This is ascribed to early recognition and intensive treatment with emetine injections and diodoquin where secondary infection is present (and it is suggested that 50 per cent of amoebic abscesses of the liver are so infected at the time of diagnosis) penicillin and emetine would appear to be a wise combination. One case with constant lumbar pain is described which suggested formation of an amoebic perinephric abscess. The pain and fever were relieved by emetine injections. The method of pneumoperitoneum is employed as a means of delimiting the lower edge of the liver. Penicillin therapy alone is regarded as of no value, but should be considered a valuable adjunct to emetine when secondary invading organisms are suspected. *P Manson-Bahr*

HAYS, T G, BROWN, R B & GODFREY, E W **Liver Abscess** *U S Nav Med Bull* 1948, Jan-Feb, v 48, No 1, 7-21, 5 figs

During five months from December 1945 to May 1946, 10 cases of liver abscess were treated in a U S Naval Hospital. Several of them illustrate many important points in diagnosis and treatment. The clinical picture may be anything but characteristic. The pain in the right lobe of the liver is usually dull and intensified by deep pressure.

Laboratory studies may be of limited diagnostic value, and liver function tests, even the icterus index, and the van den Bergh reaction, are not uniformly or significantly altered. The most reliable aid to diagnosis is provided by radiography. Elevation of the right dome of the diaphragm is purely mechanical, restriction of movement is primarily irritative and increases with proximity of the abscess to the dome. Areas of atelectasis or pneumonitis within the lung tissue, or fluid in the pleural sulcus, are secondary to the inflammatory process below the diaphragm. Serial films, showing increasing size of the liver, or progressive elevation of the dome of the diaphragm, are of particular significance.

The cases here recorded were treated by open surgical drainage, but it is admitted that some of the patients might have been cured on a more conservative régime. Seven of the ten cases were correctly diagnosed before operation. Two were operated as cases of acute cholecystitis and in one the true diagnosis was revealed post-mortem.

Three in whom amoebiasis was suspected as the chief aetiological factor returned with further complications attributable to this infection. Initial prompt but incomplete, therapeutic response to penicillin on two occasions in one case, suggested a superimposed bacterial infection, though this was not confirmed at operation and by culture. It is suggested that more intensive treatment of the underlying amoebiasis with emetine and carbarsone might have prevented recurrences. *P Manson-Bahr*

MANSON-BAHR, P **Secondary Bacterial Infections of Amoebic Abscess of the Liver** *Liber Jubilaris J Rodhain (Soc Belge Méd Trop, Brussels)* 1947, Dec, 291-301, 5 figs [13 refs]

In the diagnosis and treatment of amoebic liver abscess, the possibility of secondary bacterial infection must always be considered. In abscesses of old standing, such contamination is not uncommon. The implications of its existence are insufficiently appreciated. Early cases of hepatic amoebiasis

respond well to emetine. Later cases may fail to do so owing to bacterial infection and repeated aspiration fails to relieve these. After surgical drainage such cases recover.

There is little reference in the literature of the last 35 years to proven secondary infection of amoebic liver abscesses, and none as to the route of infection. In it does occur. In 60 of the author's cases of amoebic liver abscess, 11 were found to be bacterially infected. In only four of these could active amoebae be found in the aspirated abscess contents. *E. histolytica* cysts were recovered from the stools of 45 per cent. of patients with amoebic liver abscesses.

The author envisages the development of an amoebic liver abscess as follows. There is a massive portal invasion of the liver with amoebae producing an allergic response with engorgement and swelling of the organ to about twice its normal size. Large numbers of amoebae are distributed throughout the liver lobules but the majority are destroyed. A few survive and multiply as a focal point causing a single abscess which initially resembles a gumma or a tuberculous nodule rather than an abscess. In this solid along the amoebae multiply at the periphery and are not found in the centre. The centre of the lesion liquefies by cytolytic action; the liquefaction extends radially and the contents of the cavity become a sterile fluid pus. In some rare cases this becomes inspissated, and absorbed or calcified. The author has seen four calcified abscesses one of over 20 years duration without the patient's having been aware of its presence. Aspiration of the pus before liquefaction takes place is impossible but emetine injections kill the amoebae and the material is absorbed. After liquefaction has taken place emetine is not effective unless the pus is drained. If this pus is bacterially infected aspiration is inadequate and emetine therapy is ineffective. Surgical drainage is necessary.

The routes by which bacterial infection of the liver parenchyma may occur are—(1) by rupture of the abscess through the diaphragm and direct infection via the respiratory tract; this is probably the most common. (2) by direct absorption from the large intestine possibly by extension from the hepatic flexure of the colon in close proximity to the liver by *Bact. coli* and other intestinal organisms. (3) as part of a general septicaemia from a septic focus such as a boil on the surface of the body.

Five cases of amoebic liver abscess secondarily invaded by bacteria are cited to illustrate these modes of bacterial infection. The invading organisms identified were *Bact. coli* and a long-chain *Streptococcus Strept. viridans*, *Staph. enteritidis* and *Staphylococcus aureus*. In conclusion, the author contends that it is better to regard an amoebic liver abscess as bacterially infected until proven otherwise. Alteration in the temperature chart from an intermittent to a high remittent type is indicative of this secondary infection.

ANDERSON, H. H., HANSEN, E. L., NAM, P. P. T. & CARLIN, J. R. Amoebicidal and Pharmacologic Activities of Carbarosone Oxide (P-Carbamidophenyl-arsenous Oxide) and its Dithiocarboxymethyl and Dithiocarboxyphenyl Derivatives. *J. Pharm. & Exp. Ther.* 1947 Oct., 91, No. 2, 112-23, 11 refs.

Carbarosone has been used extensively in the treatment of amoebiasis. The corresponding carbarosone oxide and the dithio derivatives named in the title have the following formulae—

The amoebicidal action of these four substances and of emetine have been compared *in vivo* and *in vitro* by the methods previously described by the authors [this *Bulletin* 1947, v 44, 819]. Before clinical trials on monkeys naturally infected with *E histolytica*, toxicity tests were carried out on the white cells of rabbits and on various laboratory animals. The pathological effects produced were studied in some detail. In the monkey, carbarsone oxide and the above derivatives were found more active than the pentavalent carbarsone, while emetine in effective doses was not well tolerated. Details are given of the methods employed in studying the distribution of arsenic in tissues after administration of arsenicals by different routes. Carbarsone oxide gave rise to high levels of arsenic in bile, blood and urine, and smaller amounts were present in other tissues. The distribution of arsenic after dithio derivatives was somewhat different and levels were not so high. The level remained appreciable for some days after administration. The amount bound by tissues was roughly paralleled by toxicity. Fewer pathological changes were produced by the dithio derivatives than by the parent oxide. The introduction of these groupings did not, however, appreciably affect amoebicidal activity *in vitro* or *in vivo*.

I. In this series of papers is described a systematic search for new amoebicides whose structure has been based on that of emetine and of certain compounds found by PYMAN (*Rep Brit Ass* 1937, v 107, 60) to be active *in vitro*. Methods for comparing the activity of these substances *in vitro* and *in vivo* are described. For the former tests, a culture of *E histolytica* grown with a single bacterium (*Bact coli*) was maintained in culture on the horse-serum-Ringer-egg medium of DOBELL & LAIDLAW [this *Bulletin*, 1927, v 24, 363]. In the actual test the buffered horse-serum Ringer medium of LAIDLAW *et al* [this *Bulletin*, 1929, v 26, 469] was used to which the appropriate concentration of drug in sterile buffered Ringer solution was added and then a heavy inoculum of *Bact coli* and a small quantity of sterile rice starch. After incubation at 37°C overnight, the bleaching of an added drop of dilute methylene blue solution indicated that conditions in the medium were satisfactory for the growth of amoebae. A heavy suspension of *E histolytica* from the stock cultures was then added to each tube by pipette. After incubation for 3 days, the contents of the tubes were

examined microscopically for the growth of amoebae the pH of the ulcers was checked and the viability of the bacteria tested by subculture. The first two tests in which young rats of weight 20 to 30 gm. were used immediately after weaning were carried out in a manner similar to that described by JONES (this Bulletin 1947 v 41 313) by intracoeccal inoculation of 0.2 to 0.4 cc. of *E. histolytica* culture material. The present authors point out that while numerous shallow ulcers were produced in these rats which have a restricted parasite population on account of their age nothing resembling the deep disk-shaped ulcers seen in human infections was encountered. The inoculated amoebae were found to have ingested bacteria, but rarely red cells, and cysts were scanty. Natural infections of the experimental rats with an amoeba not distinguishable in fresh preparations from *E. histolytica* caused difficulty. It was believed that infection arose from cysts passed by hamsters housed in the same room. With suitable precautions, infection of the rats could be a corollary (FULTON & JONES had difficulty with similar infections in rats while carrying out amoebicidal tests and have recently reported (this Bulletin 1948, v 45 430) the results of a survey of amoebic infections in laboratory rodents—white rats, cotton rats, hamsters and Orkney voles separately housed were found to be infected very early in life, about 50 per cent. in the case of white rats before weaning. The cotton rats had been isolated since coming to Britain.) Differences in infectivity of human strains of *E. histolytica* for these young rats were noted and the infection rate in different experiments varied from 80 to 100 per cent. Drugs were generally administered in the diet for 6 days, but if it were rendered unpalatable in a promising case drug dosage by stomach tube was resorted to. The criterion of activity of a drug was the presence or absence of amoebae in the rat caeca after treatment; the macroscopic appearance of that organ was also taken into consideration. Controls were used in all experiments. The results for a series of standard amoebicides tested by both methods is given in tabular form. Emetine proved the most active drug in both cases (based on dosage given) and the relative activity of the others was in the same sequence in both tests but this was not true for all drugs. The calculation of chemotherapeutic indices showed that the curative dose of emetine was close to the toxic dose. Diodoquin had the best therapeutic index.

II A number of compounds based on structures derivable from emetine were previously synthesized by PYMAN and collaborators but proved inactive against *E. histolytica*. The present authors have prepared and tested two series of secondary diamines of the general type $\text{Ph} \cdot \text{R} \cdot \text{N}(\text{H}) \cdot \text{R}' \cdot \text{N}(\text{H}) \cdot \text{R}''$ (phenylalkylamine series) formally related to emetine, in which Ph represents a benzene ring, R a chain of CH_2 groups. This change was varied in length and structure and different substituent groups were introduced to the benzene ring. In a second alkylamine series the phenyl groups were omitted. The test methods were similar to those employed in Part I above. The results are given in very condensed form in a table and include those for tests carried out on certain trypanosomal, leishmanial and malarial infections. There is also a chemical section and in order to appreciate the effort involved in these researches the original should be consulted. Certain derivatives in the phenylalkylamine series showed activity both *in vivo* and *in vitro* and the authors discuss the effect of different substituents as well as of variations in length of the methylene chain. Broadly speaking, the results for the alkylamine series were similar. The difference in activity between soluble and insoluble salts of the bases including both the iodides was not significant. None of the compounds was so active as emetine many were irritant and it appeared that clinical trials were not justified.

III PYMAN (Rep. Brit. Ind. 145 1937 107 57) reported that 1,10-bis-(*n*-amylamino) decane ($\text{C}_{11}\text{H}_{25}\text{N}_2$) (H₁₂ C₁₁H₂₅) showed high amoebicidal

activity *in vitro* Following this observation, the present authors have synthesized a number of compounds including aromatic derivatives, based on the model of the above substance and have studied the effect on amoebicidal activity of changes in its structure as well as in those of the corresponding secondary bases and certain quaternary ammonium salts. The tests are presented as in Part II above and a chemical section is included. The parent substance showed activity *in vitro* but only to a slight extent *in vivo*. Tertiary aromatic diamines of varied structure were inactive in both tests, while the corresponding secondary aromatic diamines showed slight activity *in vitro*. Secondary araliphatic amines were active to some extent *in vitro*, but not *in vivo*, and results with this series indicated that an *in vitro* test by itself is unreliable for assessment of amoebicidal action. As shown in Part I above the two types of test give inconsistent results in the case of diodoquin (a very insoluble substance). Quaternary ammonium salts proved a little more active than the parent tertiary bases.

MILLER, A A & PECK, C R **Balantidial Dysentery Report of a Fatal Case in Assam** *Brit Med J* 1948, Mar 6, 448-9, 1 fig on pl

The authors report this case because of the rarity of balantidial dysentery, especially in India, but they refer in a footnote to 10 cases, reported by SHUN-SHIN [this *Bulletin*, 1948, v 45, 84] in the island of Rodriguez, since their article was completed.

The present case refers to an Indian sepoy of 30 who died of an acute dysenteric illness three days after admission to hospital, and five days after symptoms began. The principal clinical features were pyrexia, abdominal pain, diarrhoea and dehydration. No pathogenic organisms could be found on repeated microscopical and cultural examination, but a number of parasites were found in an ulcerated portion of the pelvic colon. The disposition and morphology of these organisms are fully described, together with the histopathology of the ulcerated colon. These parasites had the typical morphology of *Balantidium coli*. The authors point out that although the clinical, autopsy and histological features of this case were similar to those often found in amoebic dysentery, the discovery of the balantidia suggested an alternative diagnosis.

KIRSHBAUM, J D **Intestinal Coccidiosis Report of Two Cases of *Isospora hominis*** *Amer J Clin Path* 1948, Jan, v 18, No 1, 58-60, 1 fig

"During the course of examining approximately 5,000 stool specimens for parasites, in a general hospital at Espiritu Santo in the New Hebrides, two infections with *Isospora hominis* were encountered. Both soldiers were members of the same company, both manifested mild intestinal symptoms of intermittent diarrhea, malaise and loss of weight, and both responded promptly to treatment. Eosinophilia was present in both patients. The oocysts and sporocysts were the only stages seen in both the fresh stool specimens and in specimens kept at room temperature for a period of sixty-six days. The cysts were easily identified in the fresh feces emulsified in water and also by the flotation method, using zinc sulfate or table salt."

RELAPSING FEVER AND OTHER SPIROCHAETOSSES

WILLCOX, P H **Louse-borne Relapsing Fever in Persia.** [Correspondence] *Brit Med J* 1948, Mar 6, 473

The writer of this letter refers to the paper of BODMAN and STEWART [this *Bulletin*, 1948, v 45, 433] in which the claim was made that louse-borne relapsing

fever had not been reported previously in Persia. He refers to a review of the subject in 1920 by WILLCOX (*Proc. Roy Soc Med.*, 1920 v 13, Sect. of Med., 59) and LEDINGHAM (*ibid* 81) based on experiences in the 1914-18 war during which the disease was a serious problem among British Forces in Iraq and Persia both typhus and relapsing fever were endemic and were commoner than enteric fever.

Louse infestation was extremely common in the Turkish army and relapsing fever was prevalent in Kut in the winter of 1915-16. British troops did not become infected until their contact with the local population and with Turkish prisoners. It is also noted that the disease occurred in the civil and military population of Bagdad in 1917 and mortality figures are given for 1,883 cases.

It is also pointed out that LEDINGHAM (*loc cit*) had also demonstrated the correspondence in incidence curves for typhus and relapsing fever from 1917 onwards and in other respects, epidemiological and clinical, the earlier epidemic of relapsing fever corresponded closely in almost every detail with the 1944 outbreak.

Evidence is quoted to show that lice may occasionally be infective for typhus and relapsing fever at the same time and the case is mentioned of a medical officer who contracted relapsing fever 8 days after attending two cases of typhus.

BALLIF L., CONSTANTINESCO N & CHELĂRĂSCO M. Meme. Recherches des spirochétolyses dans la fièvre récurrente épidémique. (Note préliminaire). [Lysis Test in Epidemic Relapsing Fever] *Bull Acad. Méd. Roumanie*, 1945, v 19 Nos. 4 & 5, 572-5.

The difficulty of diagnosing relapsing fever during the afebrile period when spirochaetes are absent from the blood led the authors to elaborate a lysis test. In this test dilutions of the patient's serum (from 1/1 to 1/20,000) are mixed with defibrinated blood from a patient heavily infected with spirochaetes, and with guinea-pig or human complement. After incubation at 39-41°C. for 2 hours, smear or thick drop films are prepared from each dilution, and are stained by Giemsa's method. The test is considered positive when the spirochaetes show numerous acidophile granules. The organisms may degenerate into indistinguishable masses of agglutinated granules or with prolonged incubation of the mixtures, may be partially or completely lysed.

If dried blood only is available, it should be mixed with an equal volume of physiological saline and the extract used instead of serum.

The antibodies responsible for this reaction can be demonstrated at least 400 days after recovery from the disease and, as noted above, they can be recovered from dried blood. The test is therefore useful in epidemiological surveys or in field diagnosis in times of epidemics. [No evidence is offered that these lytic antibodies will react with the numerous and serologically distinct relapse strains of the spirochaetes. Without such proof, any information derived from the test could have little practical diagnostic value.]

PASTOR BOTIJA, F. Consideraciones sobre las secuelas oculares en la Lepra recurrente. epidemia de los años 1945-1946 en la Zona de Protectorado Español en Marruecos. [Ocular Sequelae of Relapsing Fever seen in the 1945-46 Outbreak in Spanish Morocco.] *Med. Conveul. Madrid* 1945, Feb. 1 11 v 2, 60-67.

The author states that though many have written on relapsing fever few have referred to the eye complications and sequelae of this disease. In the Loue-borne outbreak (1945-46) he observed certain cases which he wishes to

place on record and he refers in the present article to seven of them. The complications and sequelae mentioned are subconjunctival haemorrhage and purulent conjunctivitis, iritis and irido cyclitis and uveitis, occasionally bilateral, more often unilateral and affecting nearly always the right eye. He also saw cases, one severe, of papillitis, with pallor of disk and some atrophy. The Wassermann reaction was not tried in all cases and may have been positive, but by no means in all. The conclusion is that the lesions were due to the relapsing fever and not to syphilis. The author is of opinion that if the infection were treated properly in the early stages with adequate doses of novarsenobenzol these complications might be avoided.

LEPROSY

DOULL, J A, GUINTO, R S, BANCROFT, Huldah & RODRIGUEZ J N
Historical Inquiry as a Method of estimating the Trend of Leprosy *Internat J Leprosy* Cleveland, Ohio 1947, Oct-Dec, v 15, No 4, 369-77

The data used were collected in the municipalities of Cordova and Talisay in the province of Cebu, Philippine Islands, a detailed history being obtained for every household, including, to the utmost extent, all births, deaths, other entries and exits and the occurrence of leprosy. Sufficiently complete records were obtained for 3,204 families including 21,791 individuals 335,016 person-years of exposure and 402 cases of leprosy (of which 261 were lepromatous and 141 neural or mixed). When the period of observation is divided broadly into years prior and years subsequent to January 1st 1915, there is no evidence of any change in the total incidence rate. In the later years, however, the milder forms of macular and neural leprosy would have been more frequently observed than in the earlier period. Limiting the comparison to the lepromatous type reveals a lower rate post-1915. A more exact comparison is made by taking persons born between 1896 and 1910, and calculating their experience up to 1920, and comparing them with individuals born between 1911 and 1925, and calculating their experience up to 1935. After adjustments for age differences in the populations at risk, the resulting incidence rates of lepromatous leprosy per 1,000 person-years are: born in 1896-1910, followed to 1920, males 1.59, females 0.78, both sexes 1.18; born in 1911-25, followed to 1935, males 0.78, females 0.31, both sexes 0.54. The later born have rates only some half those of the earlier born. Further analysis of these two groups was made to show whether this downward trend occurred in leprous households as distinguished from the total population. Only those who were known to have been living in household association with lepromatous leprosy were considered as exposed and their experience was contrasted with that of those for whom no history of exposure to any type of leprosy could be ascertained. To make allowance for the incubation period, exposures only to 1915 for the first group and only to 1930 for the second were counted. The resulting rates, adjusted for age, and per 1,000 person-years were as follows: Household exposure: earlier period, males 12.8, females 9.5, both sexes 11.3; later period, males 6.3, females 3.0, both sexes 4.7; no household exposure: earlier period, males 0.80, females 0.46, both sexes 0.63; later period, males 0.43, females 0.19, both sexes 0.32. The relative reduction is slightly greater in the leprous households.

Compulsory segregation was introduced in 1907 and the observed lower rates are in accord with the view that this may have been a factor. The expenditure is, however, relatively small and other environmental changes took place concurrently—in particular a rise in the standard of living—so this interpretation of the trend is not justified.

VOX BRANT T. & FILES, Virginia S. Chemical and Histological Observations on the Influence of *Schistosoma mansoni* Infection on *Australorbis glabratus*. *J. Parasitology* 1947 Dec. v. 33, No. 4, 478-82. (19 refs.)

"Infection with *Schistosoma mansoni* does not interfere seriously with the storage of fat in the body of its invertebrate host, the snail *Australorbis glabratus*. The latter's oxygen consumption also remains normal. Infected snails have, however, a reduced polysaccharide content and this reduction is a result of a diminished storage both in parasitised and non-parasitised organs. Whether this decrease is due to an impaired carbohydrate digestion and resorption or to a toxic action by the parasites is not clear. The possibility that it is due to the food consumption of the parasites has not been ruled out completely.

KIESER, J. A. Schistosomiasis: an Educational Problem. *South Africa M. J.* 1947 Nov. 22, v. 21, No. 22, 831-3.

In this short paper the author stresses the deleterious effect of schistosomiasis [S. haematodes m.] on intelligence and vigour. The mental symptoms are so monotonously uniform in character that a diagnosis of schistosomiasis could almost be made on them alone. In children they are forgetfulness, indifference to punishment, apparent laziness and a disinclination to mental exertion combined with a sometimes very marked nervous irritability, obstreperousness and mental fatigue. This condition may be so serious that the child may be in danger of certification as mentally deficient.

Several illustrative cases are quoted, in children and young adults. Successful treatment removes these disabilities very effectively.

Charles H. Monte

BLAIR, D. M. HAWKINS, F. & ROSS, W. F. The Effect of Miracidin on Human Schistosomiasis. *J. Hyg.* 1947 Dec. 20, 911-1.

Miracidin is the hydrochloride of Miracidin (see this *Bulletin* 1948, v. 45, 567) and has been claimed by HARTMAN and GONNERT to be effective against infections with *Schistosoma mansoni* in mice and monkeys. The authors after two of them had investigated its pharmacology and to a high degree in monkeys and man, tried it on 47 patients in Southern Rhodesia infected with *S. haematodes m.*, *S. mansoni* or both.

The drug was given by the mouth as uncoated tablets, one each day after the middle meal for 8 days each week up to a maximum of 28 doses. Doses varied: children were given 100 mgm or 75 mgm at a time, the three adults received doses of 200 mgm. 14 urinary doses of 50 mgm were given to all patients to exclude absorption. The drug was well tolerated, but these doses approach

the known maximum tolerated dose for repeated administration, namely 200-300 mgm per diem

Results were poor Eight weeks after cessation of treatment only 9 of 40 with *S. haematobium*, and 2 of 11 with *S. mansoni*, were not passing eggs

This is a preliminary paper, details are to be published elsewhere

KHALIL, M & HALAWANI, A Cloroben as Snail Poison for Control of Bilharziasis—its Danger to the Rice Plant *J Roy Egyptian Med Ass* 1947, Sept, v 30, No 9, 454-60

Cloroben is an American preparation recommended for killing aquatic plants and snails Analysis indicated that it contains 61.3 per cent of ortho-dichlorobenzene as an emulsion The authors found that 50 parts per million would kill *Bulinus truncatus* and *Planorbis boissyi* in 2-3 days, but that this concentration was lethal to fish (*Gambusia*) and to rice Moreover, it is (no doubt) toxic for man and domestic animals For these reasons the authors have issued a warning against the use of this substance in small control Copper sulphate, which has been found to have a beneficial effect on rice fields by killing the algae which cause one of the important diseases of rice, remains the chemical of choice for this purpose

LIPPINCOTT, S W, ELLERBROOK, L D, RHEES, M & MASON, P A Study of the Distribution and Fate of Antimony when used as Tartar Emetic and Fouadin in the Treatment of American Soldiers with Schistosomiasis Japonica *J Clin Investigation* 1947, May, v 26, No 3, 370-78, 5 figs

American soldiers numbering 138, who had been infected with *Schistosoma japonicum* while serving in the Philippines and were still passing eggs in their faeces in spite of treatment, were given one or more courses of tartar emetic or Fouadin, equivalent to 45 mgm Sb on alternate days The latter was given intramuscularly and tartar emetic was given intravenously till a total of approximately 570 mgm of Sb was reached Estimations of Sb in body fluids, as well as of the amount and rate of excretion in urine and faeces, were made on some patients during and after treatment by the Rhodamine B method of MAREN (*Bull Johns Hopkins Hosp* 1945, v 77, 338) whereby a red Sb-dye complex is formed By this means, 0.5 microgramme of the element could be estimated in the absence of iron Towards the end of treatment, the level in plasma was approximately 100 microgrammes per litre after both drugs Twenty-eight days later, only one-fifth of that amount was present The concentration in red cells was consistently higher than in plasma The urinary excretion towards the end of treatment was somewhat higher after Fouadin, being then approximately 10 mgm per day and 2 mgm daily in faeces Antimony was still detectable 100 days later in both excretions A small concentration of Sb was present in bile Of 33 patients treated with Fouadin, 82 per cent who remained under observation had ova in their faeces 3 months later and a similar percentage were passing ova after a second course The relapse rate was 19 per cent in 59 patients after a course of tartar emetic

WRIGHT, W H, BAUMAN, P M & FRY, N The Control of Schistosomiasis Japonica VI Studies on the Chemical Impregnation of Underclothes as a Protection against Schistosomiasis Japonica *Amer J Hyg* 1947, Jan, v 47 No 1, 33-43

These studies were carried out by members of the Commission on Schistosomiasis, Army Epidemiological Board, United States Army Studies Nos

I, II III and IV have already been noted in this Bulletin while No. V has not yet been published.

The experiments and observations recorded in Study No. VI were designed to ascertain if some method could be found for impregnating the socks and trousers of combatant troops in order to afford protection to the lower parts of the body which in combatant operations would be most exposed to the danger of infection by cercariae. The experiments were carried out with various types of Army cloths which were soaked in the chemical to be tested, and then wrung out and subsequently dried. After each test, the cloths were washed with a rather more thorough technique than is usually employed by the average enlisted man to ascertain if any effectiveness had been dissipated through the washing process. Each stage in the process of impregnation and subsequent washing was carried out under carefully standardized conditions, which included calculations on the amount of the chemical taken up by the treated cloth. The resistance to penetration by cercariae of the impregnated cloths, was ascertained before and after each washing by experiments with animals but owing to the large number of drugs submitted for testing, and the relatively few suitable animals a reliable preliminary screening by *in vitro* tests was necessary. For this purpose a measured piece of the previously impregnated cloth was placed in a Petri dish, together with 4 cc. of water for 10 minutes. 10 cercariae were then added to the fluid and kept under observation for 30 minutes. Those compounds which showed the highest percentage of kill were selected for the animal tests which were of two types. In the first, the impregnated cloth was stretched tightly over a small wire basket, and the animal was placed in this cloth-covered basket which was then stood on raised supports in a vessel containing 600 ml. of water to which 3,000 : 5,000 *S. japonica* cercariae had previously been added under these conditions, about 200 ml. of the water in the bath penetrated the cloth. Exposure was for 45 minutes and samples were taken from inside the cloth after 20, 30 and 40 minutes, in order to determine whether the cercariae had penetrated. In the second method, test and control animals were anesthetized, and a small amount of water containing 500 shed cercariae was made into a pool on the cloth to be tested which was applied directly to the shaded surface of the animal's abdomen. After 45 minutes exposure the cloth was removed and the animal kept under observation for 28 days or longer after which it was destroyed and examined for *S. japonicum*. In addition to these tests of impregnated cloths the writers carried out a limited number of experiments with untreated uniform cloth, and with certain types of water repellent garments issued to the troops.

The authors summarize their results as follows —

"To determine the value of unimpregnated clothing as protection against the acquisition of schistosomiasis japonica, *in vitro* and *in vivo* tests were carried out with 31 compounds or combinations of compounds. Types of uniform cloth tested included 8-ounce cotton santon cover 1 lb. herringbone twill cloth, olive drab woolen trouser cloth, cotton gloves and 1100 socks. A total of 537 animals was utilized in the exposure tests. A number of the compounds were discarded after *in vitro* screening tests while others failed to give good protection on the animal tests.

"An emulsion of 4.5 per cent benzyl benzoate with 0.5 per cent Tween 80 in water proved to be the most effective compound. Cotton trouser cloth and herringbone twill cloth impregnated with this emulsion provided protection through 4 washings of the cloth. Dibutyl phthalate in 5 per cent emulsion with Tween 80 in water afforded protection with cotton trouser cloth, herringbone twill cloth and olive drab woolen trouser cloth after two washings of each

type of cloth. There is reason to believe that this compound might be equally effective or more effective than benzyl benzoate. Good results were obtained also with the gas protective chemical, CCl_4 (this is not a chemical formula but a secret designation). This compound protected through two washings of herring-bone twill, cotton glove material and cotton socks. Since the latter fabric is easily penetrated by schistosome cercariae the protection afforded by the chemical is of considerable significance and indicates that it might persist even after additional washings.

The impregnation of clothing with certain water repellent compounds gave good results in some instances. However, this protection was gradually lost when the cloth was washed. In general, such compounds gave results inferior to those obtained with miticidal compounds.

The relative degree of protection afforded by various types of uniform cloth varied with the weave of the cloth and the amount of the chemical taken up during the impregnation process. From a practical standpoint, impregnated woolen uniform cloth would provide protection over a longer period of time and after more washings than either the cotton unit or the herring-bone twill cloth. The latter would appear to offer the best protection against schistosome cercariae of the 3 standard types of uniform cloth.

R. M. Gordon

WRIGHT W. H., BULFINCH P. M. & LEE, N. The Control of Schistosomiasis Japonica VII. Studies on the Value of Repellents and Repellent Ointments as a Protection against Schistosomiasis Japonica. *Trans. J. Hyg.* 1948 Jan. 47 No 1 11-52 1 fig.

The experiments recorded in this paper were designed to supplement cloth impregnation experiments described in the previous paper and to develop a method for protecting the unclothed parts of the body against schistosome cercariae. Liquid preparations although they protected when applied undiluted and allowed to dry on the skin proved less satisfactory than the various ointments which were used in 16 experiments on 348 mice exposed to infection with the cercariae of *S. mansoni* and *S. japonicum*. In the case of animals exposed to *S. mansoni* and *S. japonicum* the vertical immersion of the rodent in water proved satisfactory but owing to its surface haunting habits other methods which are fully described by the authors had to be used in the experiments with *S. japonicum*. All of the ointments employing dimethyl phthalate, dibutyl phthalate, benzyl benzoate, Rutgers 612, Indalone or 2-phenylcyclohexanol either singly or in combination with the exception of the ointment containing copper silicate dimethyl phthalate and Rutgers 612 and the ointment containing 5 per cent of dimethyl phthalate and 5 per cent of Rutgers 612 afforded protection against infection as did a combination of copper acetate 1 per cent dimethyl phthalate 5 per cent and Rutgers 612 5 per cent. Two of the ointment bases in themselves offered little resistance to the cercariae, so that the protection conferred by the repellent ointments was not merely mechanical. It is clear from the results of these carefully conducted experiments that certain of the repellent ointments which were tested are of considerable value in protecting individuals exposed to schistosomiasis. The authors point out however, that many additional tests are needed, particularly as regards the length of time such ointments remain effective during continuous exposure to water or under conditions causing copious perspiration.

R. M. Go

microfilariae. The results of surveys made in this and other places are shown in the table.

| Locality | Positive skin smears, per cent. | Nodules, per cent. | Blindness, per cent. |
|-----------------|------------------------------------|-----------------------|--|
| Suez Rest-house | 80 | 3-4 | Under 1 |
| Raffia-River Bo | 8 | 4 | 4-5 |
| Raffia-Park | 50 | 20 | This probably includes all three localities |
| Perli | 25 | 3 | |
| Pongo | 90 | 46 | |
| Wau | 19 | — | 10 Reported low |

The number of persons examined was usually between 30 and 80. The nodules were mostly on the side of the chest or near the iliac crests and great trochanters, but many patients had no nodules. The skin conditions included xeroderma, and a condition like *craw-craw*. Blindness occurs and is definitely due to onchocerciasis in some cases. It is often preceded by a period of night blindness. Hydrocele and scrotal elephantiasis are extremely common in the areas of onchocerciasis in the Sudan but *W. bancrofti* infection is extremely rare.

F Hawk

MAZZOTTI L. & HEWITT R. Tratamiento de la onchocercosis por el cloruro de 1-diethylcarbamil-4-methylpiperazina (Hetrazan) [Treatment of Onchocerciasis by Hetrazan.] *Medicina* Mexico, 1948, Jan. 25 v 28 No. 548 39-42.

The authors following up the success recorded by SANTIAGO-STEVENSON and his colleagues in filariasis due to *W. bancrofti* [this Bulletin 1948, v 45 353] have tried Hetrazan (1-diethylcarbamil-4-methylpiperazine) in 6 patients infected with *Onchocerca* in doses of 2 mgm. orally per kilo body weight thrice daily. Four took it for 15 days and two for 21 days. Cutaneous biopsy was made thrice a week for 45 days and thereafter twice weekly. Before the treatment was begun, microfilariae were numerous, as many as 60 in a specimen 6 mm. square. Within 24 hours of beginning the treatment four patients showed a generalized oedema, especially of the face and upper part of the chest with fever, general malaise, pruritus and joint pains. In these cases the drug was suspended for 3 days, by which time these symptoms had disappeared; they were regarded as allergic. Microfilariae were much fewer even after 24 hours. Biopsies during the next 6 weeks revealed in patient No. 1 one microfilaria on the 17th day, one in No. 2 on the 14th day, 5 in No. 3 between the 5th and 8th days. This patient had to leave hospital on the 17th day and on that day 6 cutaneous biopsies were carried out and all were negative. No. 4 showed 3 microfilariae on the 6th day.

The other two patients were given one-third the dose on the first day, two-thirds on the second day and thereafter the full dose for 21 days. After 48 hours and during 90 days' observation an occasional microfilaria only was seen. One of these patients had three nodules which were later extirpated. Nos. 1, 3 and 4 also had nodules which, when removed from 14 to 39 days after the drug treatment was started, were found to contain adults normal in appearance and living embryos. In one nodule the adults seemed to be normal, but microfilariae which were present in large numbers, were all dead. [see OLIVER-GONZALEZ & HEWITT below]

ALICATA, J E & KARTMAN, Anna Y **Incidence of Oxyuriasis among a Group of School Children in Honolulu** *Hawaii Med J* 1948, Jan-Feb, v 7, No 3, 214-15, 2 figs

"An examination of a group of 138 children, aged $2\frac{1}{2}$ to 7, attending school (nursery to first grade) in Honolulu, showed 31.1 per cent to be positive for pinworms on two swab examinations. Calculated on the basis of seven swabs, believed required to reveal most cases, the incidence of infection would probably be about 38 per cent. The number of positive cases was found to be equal among the two sexes. Children of Caucasian ancestry appeared to show a higher incidence of infection (40 per cent) than those of Oriental ancestry (21 per cent). The results indicate that oxyuriasis is probably common in this community and represents one of the problems of public health importance."

OLIVER-GONZÁLEZ, J & HEWITT, R I **Treatment of Experimental Intestinal Trichinosis with 1-Diethylcarbamyl-4-Methylpiperazine Hydrochloride (Hetrazan)** *Proc Soc Exper Biol & Med* 1947, Oct, v 66, No 1, 254-5

Since Hetrazan has been used with good results in filariasis [this *Bulletin*, 1948, v 45, 353], it was considered worth testing it in *Trichinella spiralis* infections in white rats.

Between 1,000 and 1,300 *Trichinella* larvae were given by stomach tube and 24 hours later a course of Hetrazan was started, a dose on the basis of 200 mgm per kilogramme body-weight was given by stomach tube 3 times a day for 5 to 10 days. Rats were killed after 5, 10 and 30 days and the intestines and muscles were examined for worms and larvae.

After 5 days, an average of 91 worms were recovered from the intestines against 481 in the case of untreated controls. After 30 days the average number of larvae recovered from the muscles in the two groups of untreated animals was 31,200 and 26,100 compared with 320, 112 and 2 in three groups of animals treated for 5, 10 and 20 days, respectively.

Hetrazan is relatively non-toxic in man and it is thought possible that, as in the case of filariasis, the effective dose in man may be lower than that required in the rat.

[In the table, it is shown that after 10 days 312 worms were recovered from the intestine of the treated rats against 61 in the untreated rats. There is no comment in the text on this apparently paradoxical observation.] [See also MAZZOTTI & HEWITT, above]

DEFICIENCY DISEASES

MACNAMARA, O D **The Effect of Diet and Helminthic Treatment on African School Children** *Trans Roy Soc Trop Med & Hyg* 1948, Jan, v 41, No 4, 519-24

The African child in central Nigeria is undernourished, and usually suffers from helminthic infection—most commonly hookworm and urinary bilharzia. One hundred and sixty-five school-children were divided into 3 groups: a control group received no treatment of any kind; a second group was given extra food at school; the supplement was calculated to produce an adequate and well balanced diet; a third group was treated for helminths with oil of chenopodium and tartar emetic. The period of observation was 100 school days. The group which had extra food showed an average weight gain of 3 lb 10½ oz,

compared with 1 lb 10½ oz. in the control group and 9½ oz. in the group treated for worms. There was no significant difference between the groups in the gains in height. In the supplemented group, there was a significantly greater increase in chest circumference and an increase in endurance as tested by hanging from a bar. General health was also better in this group and signs of vitamin deficiency disappeared. There was no improvement of general health in the group given antiparasitic treatment.

REID J. A. & WILSON T. Report on Nutrition, and Discussion of the Main Causes of Death, "F" Force, Thailand. *J. Roy Army Med. Corps* 1947 Oct., v 89 No 4 149-63.

The story of "F" Force Thailand, is now fairly well known. As a result of appalling living conditions, forced labour, cholera, dysentery, malaria and deficiency disease 44 per cent. of the force of 7 000 men died in a year. Anyone who reads this paper must feel admiration for the authors and those who worked with them when it must have seemed unlikely that any of them would ever return to civilization, they continued to collect data and to keep records in face of immense moral and material difficulties.

Major Reid and Captain Wilson give a general description of the conditions to which "F" Force were exposed but their chief emphasis is on nutrition. The diet issued by the Japanese consisted mainly of highly-milled rice with some dried beans. Meat, when provided, was usually in a state of decomposition. Supplements were almost unobtainable but in some camps green leaves and wild gourds were eaten. Analysis of the diet shows that 80 per cent. of the energy was derived from carbohydrate, and 90 per cent. of this from highly milled rice. The protein intake was in the region of 30-50 gm., mainly of vegetable origin. Fat and vitamin A were almost completely absent. The average daily amounts of vitamin C, riboflavin and nicotinic acid were about 3.0, 0.7 and 6 mgm. respectively. The thiamin non-fat-calorie ratio (the total amount of thiamin in the diet (µgm.) divided by the non-fat calories never exceeded 0.3 and was usually below 0.4. The value given by WILLIAMS and STILES as the minimum necessary to protect against beriberi is 0.3. It is not surprising that under these conditions beriberi was widespread and accounted for 13 per cent. of the deaths. 11 per cent. more were attributed to beriberi complicated by dysentery. The diagnosis of beriberi was based mainly on the presence of oedema, which was almost universal. Acute cardiac beriberi was common, but the dry neuritic type was rare.

Another very common condition, attributed to malnutrition, was tropical ulcer. The cases improved, and were less frequent when rice polishings became available. A most important observation was the rarity of diseases caused by deficiency of the B₂ vitamins, such as scrotal dermatitis and glossitis, painful feet, paraplegia and amblyopia. Many of the members of "F" Force had suffered from these conditions while in Changi. Men who had glossitis or scrotal dermatitis when they left Singapore recovered on the train journey or soon after reaching Thailand. The suggestion has been made that in some way this may be related to the low calorie intake. BRAGG in Singapore (this Bulletin 1947 v 44 114) observed that signs of riboflavin deficiency appeared mainly in the relatively well-nourished.

The authors state their conclusions as follows: "In our opinion—and we think it is shared by every M.O. on this expedition—the gross inadequacy of the Thailand diet in conjunction with the merciless compulsion to exertion, outweighed in importance all other causes of death."

[This opinion is of value, since there are still many parts of the world where the population is exposed to similar if less serious conditions of malnutrition.]

and disease Any experience is important that indicates where to attack the vicious circle that these acting together, so easily set up In the case of "F" Force, it is permissible to speculate that some of the cases of diarrhoea diagnosed as dysentery may in fact have been caused by malnutrition (See MCKENZIE, this *Bulletin*, 1940 v 37, 809)] J C Waterlow

EPSTEIN, S Observations on Beriberi Heart Disease *Amer Heart J* 1947, Sept, v 34, No 3, 432-40, 5 figs [23 refs]

A case is described of a middle-aged woman, who for many years had been living on large amounts of alcohol and very little food On admission to hospital she had signs of congestive heart failure and a macrocytic anaemia with achlorhydria Both conditions responded to treatment with vitamins and a full diet

The diagnosis of beriberi was based on the following evidence

- 1 the dietary history,
- 2 the presence of signs of malnutrition (glossitis cheilitis) but not neuritis
- 3 the presence of cardiovascular changes considered to be characteristic of beriberi enlargement of the heart, increased output, pistol-shot sounds, raised venous pressure and low voltage in the electrocardiogram,
- 4 the response to treatment, described as specific 100 mgm of thiamin, 150 mgm of nicotinic acid, and 200 mgm of ascorbic acid were given daily, together with vitamins A and D, blood transfusions and a full diet

[In recent years workers in America have attempted to define criteria for the early diagnosis of cardiac beriberi (see BLANKENHORN, *et al*, this *Bulletin*, 1946, v 43, 945) This is difficult, because the cardiovascular changes are not specific In the case described above they could, as the author admits, be attributed to anaemia—an explanation which is not ruled out by the fact that the condition of the heart improved before that of the blood (see HUNTER, A, *Quart J Med*, 1946, v 15, 107) In the present state of knowledge there seem to be only two convincing tests for beriberi, a dramatic response (within a few hours) to parenteral administration of thiamin, and an increase in pyruvic acid in the body fluids, either at rest or after mild exercise (see LU and PLATT, *Biochem J*, 1939, v 33, 1538)] J C Waterlow

SPRUE

COOKE W T FRAZER, A C, PEENEY A L P, SAMMONS, H G & THOMPSON, M D Anomalies of Intestinal Absorption of Fat II The Haematology of Idiopathic Steatorrhoea *Quart J Med* (n s) 1948, Jan, v 17, No 65, 9-24, 2 figs on 1 pl [65 refs]

This paper represents a study of the haematology of 45 cases of idiopathic steatorrhoea and contains observations on the aetiological factors concerned. Diagnosis has been made on the history, the presence of a characteristic haematological and abnormal electrolyte picture excess faecal fat, flat glucose and chylomicrograph curves and low fasting serum lipoids

In 42 patients, the presence of a fat absorption defect was determined by a fat balance technique Most hypotheses concerning the anaemia in idiopathic steatorrhoea have been based upon the unitarian theory of the aetiology of the macrocytic anaemias, but the similarity between the anaemias of steatorrhoea and pernicious anaemia are superficial and a close relationship between them could not be established in this series Although minor differences may be seen

in the morphology of the peripheral blood and in Price-Jones curves, more significant differences are in the high incidence of free hydrochloric acid in the gastric contents and the demonstration of intrinsic factor in the gastric juice of one patient. Furthermore refined liver extracts did not produce a reticulocyte response in the blood picture even in those presenting sternal marrow findings identical with those in pernicious anaemia.

Minor degrees of iron-deficiency were remedied in some but the finding of a low colour index or low mean corpuscular haemoglobin concentration was not an indication that such blood pictures could be corrected by administration of iron alone. A consistent feature has been decreased fragility of red cells to hypotonic saline similar to that noted in a number of anaemias. The rapid fall in red cells and haemoglobin that may occasionally be noted suggests a haemolytic process comparable with that demonstrated in pernicious anaemia, and the finding of increased erythropoietins in the bone-marrow with relatively static peripheral blood counts might also be regarded as evidence of a maturation defect.

Serum-bilirubin levels have not been markedly abnormal. Total pigment excretion in the urine and faeces was within normal limits. There is therefore little evidence of increased red cell destruction in idiopathic steatorrhoea.

The conception that faults in fat absorption may give rise to blood disorders opens up wide fields of investigation. The lack of correlation between the haematological improvement and the fat absorption defect and the occurrence of death with a relatively normal blood picture might be considered as evidence against the anaemia being secondary to the underlying fat absorption defect. It can be shown, however, that there are aetiological differences between the various types of defect. Thus the absorptive defect persists in idiopathic steatorrhoea, whereas in sprue and pellagra the defect may disappear entirely. It seems that qualitative changes in fat absorption may occur in the absence of any alteration in the total amount of fat absorbed. It may be as is suggested by the recent demonstration of the action of folic acid and thymine that the reticulocyte responses have been due to the replacement of temporary deficiencies of various accessory factors which were conditioned by or dependent on, an underlying fault not affected by treatment.

[For Part I see this *Bulletin* 1948, v 43 948.]

P. M. LOW-BUSH

I. DAVIDSON, L. S. P. & GIRDWOOD R. H. The Imbalance of Vitamins with particular reference to Folic Acid. *Lancet*. 1948, Mar 6 360-63 (15 refs.)

II. *Lancet* 1948 Mar 6 371 2. Folic Acid and the Nervous System.

I. In two patients with pernicious anaemia and three with sprue who were treated with folic acid, various signs of deficiency of the vitamin-B complex arose. These signs did not improve until folic acid was supplemented with, or superseded by, liver or liver extracts. The authors writing from the Uni. of Edinburgh, have found neurological changes in 8 out of 23 cases of pernicious anaemia treated with folic acid alone.

The three cases of the sprue syndrome are of special interest. The first was in a patient with idiopathic steatorrhoea who developed a mild peripheral neuritis; treatment with folic acid coincided with steady deterioration of neurological features, despite improvement of assimilation from the alimentary tract and oral and parenteral administration of large amounts of thiamine. In addition, signs of riboflavin deficiency developed. The second appeared to be a case of tropical prue in a patient from N. Africa in whom partial colectomy had been performed for megacolon. While the patient was undergoing folic acid treatment signs of peripheral neuritis developed. When L. was

treated with proteolysed liver by mouth supplemented with intramuscular injections of thiamin, riboflavin and nicotinic acid by the mouth, signs and symptoms of peripheral neuritis steadily improved. The third [referred to below] was a case of tropical sprue from India. On folic acid being given by the mouth, 50 mgm daily, the intestinal symptoms responded rapidly, but within a week a fiery red rash of butterfly distribution appeared on the patient's face, cheilosis, and glossitis also occurred. There was severe mental depression. No response was obtained to nicotinic acid, but combined therapy of folic acid and parenteral liver caused the dermatitis to subside in four days. When liver injections were discontinued, the dermatitis recurred, but it disappeared when folic acid was discontinued. The implications of this curious anomaly and the possible underlying principles have already been discussed.

ii. One of the surprises of treatment with folic acid has been the complete failure of this anti-anaemic substance to influence the changes in the nervous system that occur in many patients with pernicious anaemia.

It is possible, as HURST argued, that changes in the haemopoietic and nervous systems are due to deficiencies of different factors, both in some way connected with achlorhydria. In support of this, it is to be noted that some patients with pernicious anaemia have no detectable involvement of the central nervous system, and others with combined tract degeneration of the spinal cord who show no anaemia. But even this does not explain why these nerve changes should appear in those whose blood has been restored to normal by folic acid. This acute cord involvement is something quite new. But when the correct treatment with liver is substituted, recovery of the nervous system is quicker than is normal in the naturally occurring combination of pernicious anaemia with postero-lateral cord sclerosis. Some have even suggested that folic acid may in some way interfere with the metabolism of the conducting tissue of the nervous system.

For the curious action of folic acid in reproducing pellagrous symptoms, including dermatitis in a sprue patient reported by DAVIDSON and GIRDWOOD [above], different explanations are suggested.

In the United States, ROSS, BELDING & PAEGEL, (*Blood*, 1948, v 3, 68) observed that, on the whole, the patients who exhibited signs of posterolateral tract disturbance were those receiving the larger doses and that it persisted as long as folic acid was taken. Is it possible that folic acid denies to the nervous tissue an essential substance, in much the same manner as sulphonamides block the utilization of *p*-aminobenzoic acid in bacterial metabolism? Davidson and Girdwood think that treatment with one member of the vitamin B complex may sometimes bring out signs of deficiency of others, and that disproportion of vitamin B members might be responsible for the appearance of peripheral neuritis and of pellagrous symptoms in steatorrhoea and that some similar mechanism might explain damage to the posterolateral tract during treatment of pernicious anaemia with folic acid. Liver extract may act by "liberating" the appropriate vitamins from "conjugated" forms.

At the present moment, the hypothesis of Ross *et al* in the United States appears the most likely, as the Edinburgh series of cases of steatorrhoea had possibly multiple deficiencies. The connexion between subacute combined cord degeneration and vitamin B deficiency is not proved, as was shown by Spies' patients with nutritional anaemia who were kept on a deficient diet and treated with folic acid (SPIES *et al* this *Bulletin*, 1948, v 45, 462).

The lesson is clear—namely that, whether alone or with liver extract, folic acid must not be given to patients who show any signs of involvement of the nervous system, and the idea that folic acid and liver extract together are preferable to liver alone is negatived. [See also this *Bulletin* 1948, v 45, 360.]

VENOMS AND ANTIVENOMS

- MOLE, R. H. & EVERARD, A. Snake-Bite by *Echis carinatus*. *Quart. J. M. I.* 1947 Oct. New Ser. v 18, No. 64 291-303 3 figs. [20 refs.]

This is an account of clinical and laboratory findings in two cases of snake bite treated in the R.A.F. General Hospital, Karachi. The snake responsible for the bite was not positively identified in the first case although strong circumstantial evidence is provided that it was *Echis carinatus*. This snake was identified in the second case.

The first patient was bitten in the right ankle and did not report until 8 hours later, by which time the right foot and leg up to the knee were swollen and patchily discoloured by extravasated blood. The popliteal pulse was not palpable. The patient collapsed after the intravenous administration of 5 cc. polyvalent antivenom serum (hasauli). His condition deteriorated and by the second day the coldness and pulselessness of the affected foot suggested that gangrene was developing. Expectant treatment was carried out, and in view of continued haemorrhages (urine and faeces both contained blood) blood transfusion was started. The patient improved but on the fourth and fifth days, although the circulation in the right leg had improved, haemorrhages from the various skin lesions and in the urine became more singly profuse. At this stage as on the second day blood platelets were almost absent. He subsequently had two attacks of pallor and restlessness which were considered to be due to pulmonary infarcts, and suffered two extensor spasms of the limb and trunk but on the sixth day he improved and the bleeding stopped suddenly. An hour later transfusion was stopped. Blood was present in the urine until it disappeared suddenly on the eighth day. Consciousness was interrupted by a mild paralytic state.

On the second day the platelets were too few to count and plasma fibrinogen was reduced to less than 10 mm. per cent. Clotting time of venous blood was greatly increased or normal and the clot showed only a few tiny fibrin

strands" The icteric index was 11. The platelet count was still very low on the third day, but after that began to improve. By the fifteenth day, both the platelet count and the fibrinogen content of plasma were normal. The icteric index rose to 22 on the sixth day and was 12 on the fifteenth. The haemoglobin percentage was 96 on the second day, 70 on the third, 75 on the sixth and thereafter rose to normal.

Benzoate detoxication tests were carried out on three occasions in the first case over the second three weeks of the illness. The results indicated "prolonged impaired hepatic function". Similar tests on the third day demonstrated considerable reduction in excretion of hippuric acid, this was still evident to a much less marked degree on the 20th day.

The second patient was bitten in the thumb. The snake was killed and identified. The bite wound was incised and an intermittent tourniquet applied to the arm within 15 minutes. Half an hour later, 10 cc polyvalent antivenin (? Haffkine) was administered intravenously. Five hours after the bite the patient complained of abdominal pain and retching. A further dose of antivenin was given and blood examinations were made. Recovery followed, but convalescence was slow. Six hours after the bite, the plasma fibrinogen was normal but there were too few platelets to count. Eight hours later, platelets numbered 15,000 per cmm, and thereafter returned to normal by the third day.

The authors suggest that *Echis* venom has a pronounced effect on liver function and on "capillary function", as illustrated by the haemorrhages and thrombocytopenia. Because in the first patient the bleeding into the urine continued for two days after bleeding from other sites had stopped, they suggest that the venom is excreted by the kidneys. In spite of increased clotting time, they regard venous thrombosis to be the cause of the "intensity of the oedema and absence of any detectable circulation", in the affected limb in the first patient. No fibrolysin was detected, so that the lack of fibrinogen was probably related to failure of production in the liver. The platelets were probably being produced in normal numbers, but "were consumed in some way directly or indirectly by the action of venom".

In discussing treatment, the authors stress the importance of administration of antivenin. Continued blood transfusion is recommended in order to maintain blood volume. They advise forcing fluids by mouth to induce a high urinary output, hoping in this way to assist in the elimination of the venom.

[The important point made in this paper is the emphasis on the value of early and continued blood transfusion. It is a pity that the snake was not identified in the first case. The arguments advanced in support of the view that the venom is excreted in the urine are surely not valid. The evidence merely indicates severe damage to the renal vessels. In any case it is unlikely that venom is excreted as such. The findings in the blood are hardly compatible with the suggestion that venous thrombosis occurred in the leg of the first patient.]

The statement that "a British pathologist in West Africa was bitten on the finger by a Russell's viper" is remarkable in that, so far as the reviewer knows there is no other record of the presence of this species (or genus) in West Africa.]

B. G. Maegraith

MARQVARD, H. Saenkningsreaktionen ved Hugormebid [Stabilizing Action of the Venom of *Vipera berus berus* on a Blood Suspension after Bites from the Viper] *Nordisk Med* 1948, Mar 19, v 37, No 12, 588-9. French (summary)

BERGENHEM and FAHREUS (1936) and Bergenhem (1938) have demonstrated the stabilizing power of lysocithin in a pre-haemolytic dose on a blood suspension *in vitro*. Because of its lecithase content, cobra venom has the same

stabilizing action. In 10 hospital patients who had been bitten by *Lycra borus lenus* 1st to 4 hours before it was found that the hyocithin formed by the lecithase in the blood suspensions were stabilized. It is believed that venom is the stabilizing substance. Antivenom serum given later than an hour after the inoculation of venom does not check the stabilizing action. Hyocithin already formed is not adversely affected by the antivenom serum but serum given half an-hour after the inoculation of venom evidently restricts the action of the lecithase because in this case the formation of hyocithin and its stabilizing action are clearly reduced.

GRASSET E. Le venin de *Bitis nasicornis* son anavenin et préparation d'un sérum spécifique. [The Venom of *Bitis nasicornis* and the Preparation of a Specific Antivenom.] *Liter. Jubilaris J. Rodkain (Sec. Belge Méd. Trop. Bruxelles)* 1947 Dec., 225-40 3 figs. [15 refs.]

Bitis nasicornis Rhinoceros Viper River Jack, the Ibele or Bata of the Belgian Congo exists over much of tropical Africa. The author has tested the toxicity of its venom on white mice, guinea-pigs, rabbits and pigeons by various routes, intravenous, subcutaneous and intramuscular. Comparing it with the venoms of *B. aridus* and *B. gabonica* it is less toxic than either to mice and guinea-pigs, but to rabbits it is equal to that of *B. aridus* but less than that of *B. gabonica* while in pigeons the toxicity is practically the same in all three. Death is preceded by increasing dyspnoea, convulsions and, at times, the passing of bloody fluid per anum, and at autopsy extensive haemorrhage is seen in all the organs. Animals which survive show extensive haemorrhagic oedema, necrosis and scarring at the site of inoculation. Antivenene is obtained by injecting horses with increasing doses of ana. venom (venom plus formal) and a compound antivenene can be produced by inoculating with the venoms (or anavenoms) of *B. aridus*, *B. nasicornis*, *B. gabonica* and *V. jelskii* but the antitoxic action of the compound varies considerably. For example 1 cc. of a product thus prepared neutralized respectively 1 the above 22, 9.5, 23 and 2 mgts.

H Harold Scott

SERGEANT EL. Abris des scorpions. [The Shelter Habits of Scorpions.] *Arch. Inst. Pasteur d'Algérie*, 1947 Sept. Dec. v 23 Nos. 3 + 208-9 " figs.

The author studied the types of shelter preferred by the three commonest varieties of Algerian scorpions, *Priocnemis australis*, *Buthus occidens* and *Scorpio maurus*. In all, 11 608 observations were made.

The scorpions were studied in experimental cages each of which was provided with a darkened and a light shelter the latter being covered with clear glass. Each type of shelter was constructed in three different forms, namely (1) horizontal platform raised 3 mm. from the ground (2) the same resting 1 an angle against the side of the cage, the upper end being 4 cm. from the ground and (3) the same, with the three sides closed in with cardboard thus, in the case of the dark shelter the "penthouse" was completely obscured, while the light one was illuminated by the glass plate.

It was found in this way that 90 per cent. of the scorpions preferred the dark to the clear shelter and 60 per cent. preferred the "contact" platform to the "distant" one.

This supports the findings of JEANNEL, quoted by BERLAND in his book *Les Scorpions* namely that scorpions which find a refuge under stones during the daytime like above all to have some solid body below and under them.

DERMATOLOGY AND FUNGUS DISEASES

BAKER, R. D. **Tissue Changes in Fungous Disease** *Arch Pathology* 1947; Nov, v 44, No 5, 459-66

In a comparison of the common tissue responses in fungous diseases, the author has chosen to subdivide the reactions into 5 groups, based upon the presence of suppuration, macrophages, giant cells, caseous necrosis and fibrosis. All these features commonly occur in North and South American blastomycosis, coccidioidomycosis and in sporotrichosis. In actinomycosis, nocardiosis, maduromycosis and chromoblastomycosis, similar reactions occur but without caseation. Suppuration is usually absent in histoplasmosis and in cryptococcosis. Acute inflammation with necrosis is prominent in mucormycosis and in aspergillosis. There is either no reaction or only a low-grade chronic inflammation in moniliasis or in dermatophyte infection, unless there is invasion of deep structures.

Presence of giant cells may be determined partly by the large size of fungal elements. The action of liberated endotoxins, and the development of hypersensitivity to such products, may influence cytological response. The chronicity and extent of fibrosis are partly determined by the persistence of living organisms, both free in tissues or within macrophages.

The author fails to demonstrate any one tissue change which is characteristic of fungous infection, whereas the diversity of both active and passive reactions is illustrated.

R W Riddell

BAKER, R. D. **Experimental Sporotrichosis in Mice** *Amer J Trop Med* 1947, Nov, v 27, No 6, 749-69, 10 figs on 6 pls

Groups of mice were inoculated with saline suspensions of strains of *Sporotrichum schenckii* grown on glucose agar. Intraperitoneal injection produced thin whitish plaques on the spleen and also peritoneal nodules which had increased up to 2 mm diameter by the second week, with later peritesticular caseation. Minute grey hepatic foci appeared by the third week, sometimes the lungs were involved. Gross lesions did not change after about 4 weeks. Organisms were present in large numbers in retrosternal lymph nodes and in reticulo-endothelial cells of the liver and other organs. Haematogenous dissemination occurred in the first week. Unlike the findings in human sporotrichosis, direct examination of fresh material in 10 per cent NaOH and in lactophenol blue or Gram-stained smears, showed numerous organisms almost as frequently as did cultures, which were usually positive even in mice inoculated over 100 days before. Death occurred in about 3 weeks with mainly peritoneal and hepatic lesions, or was delayed until about 12 weeks when lesions were generalized.

Injection into the hind paw produced an abscess which ulcerated in the second week. Suppuration occurred in popliteal lymph nodes and osteomyelitis developed. Organisms were readily demonstrated by microscopy and culture. Spontaneous recovery was possible or haematogenous spread caused death in 2 or 3 months.

Similar results were obtained with the use of diluted pus from human sporotrichosis. The mouse, like the rat, may be used for experimental and diagnostic work and is more readily infected than the guinea-pig or the rabbit.

SANCHEZ MARLOQUIN A. & DE LOS ANGELES GONZALEZ, M. Estudio micológico de 16 casos de Esporotricosis en la ciudad de México. [Mycological Study of 16 Cases of Sporotrichosis in Mexico City] *in: Escuela Nac. Ciencias Biol. Mexico*. 1945, May 15 v. 4 No. 1 19-40 5 figs. [Numerous refs.]

The English summary appended to the paper is as follows:—

Sixteen cases of sporotrichosis in Mexico City are studied, classifying them in three different types: localized lymphangitic, disseminated subcutaneous and epidermal.

Sporotrichum schenckii (Hektoen and Perkins, 1900) was isolated and identified as the etiologic agent. The morphological and biochemical characteristics of the parasite are described, pointing out its particular pleomorphism and the impossibility of establishing taxonomic differences, exclusively on the basis of biochemical properties.

Finally biopsies of subcutaneous nodules were performed and studied in two of the cases.

LAWRIER T. A. Localized Coccidioidal Osteomyelitis. *New England J. of Med.* 1948 Jan. 29 v. 238 No. 5 150-52, 1 fig. [20 refs.]

"A case of localized coccidioidal infection of the os calcis that did not respond to general and local therapy is presented. Amputation of the extremity was followed by highly satisfactory wound healing without further dissemination.

MENDOZA, J. T. Histoplasmosis: Report of a Case. *Monthly Bull. Bureau of Health* Manila. 1947 Jan. v. 23 No. 1 33-40 1 folding chart

"1. A case of histoplasmosis, the third of this disease diagnosed in the Philippines is reported.

"2. The etiology and manifestations of the disease are briefly described.

"3. It is probable that there are more cases of this disease here but they remain unrecognized due to lack of previous knowledge on its recognition. This case is therefore reported to make the local medical profession and the public histoplasmosis conscious."

HEAT STROKE AND ALLIED CONDITIONS

DAILY W. M. & HARRISON T. R. A Study of the Mechanism and Treatment of Experimental Heat Pyrexia. *Amer. J. Med. Sci.* 1948 Jan. 15 No. 1 42-53 7 figs. [22 refs.]

This paper begins with a review of the literature on heat pyrexia. From this it emerges that there are three problems as yet unsolved: 'why do patients stop sweating?' 'what is the mechanism of the circulatory collapse that is first found?' 'what is the most effective means of reducing the temperature?' In animals, the mechanism of evaporative cooling differs considerably from that of man, and therefore investigation of the first question—the failure of sweating—was not possible.

Cardio-vascular changes were studied in anaesthetized dogs in a chamber heated to 45-50°C. Arterial and aortic blood pressures were recorded, the oxygen content was measured of arterial blood and of venous blood from superior vena cava, the hepatic vein and the right atrium. Total oxygen consumption

was also measured, and cardiac output was calculated by the Fick principle. As the body temperature rose, three clinical stages could be distinguished up to about 40.5°C (105°F) there was increasing excitement and the skin was flushed. From 40.5° to 42°C (105–108°F) the flush increased and petechiae appeared, hyperpnoea was extreme, movements were poorly co-ordinated. At about 43°C (110°F) convulsions and coma occurred, the flush gave way to an ashen grey pallor, with depressed respiration. As the pyrexia developed, venous pressure remained unchanged, arterial pressure, measured in the right atrium, "grey" stage, when it fell to shock levels. Oxygen consumption and cardiac output rose steadily with increasing body temperature, but both fell steeply in the terminal "grey" stage. The circulation through the skin, as measured by the arterio-venous oxygen difference increased in the initial stages while that through the viscera was low. This suggested that cutaneous vasodilatation was compensated by splanchnic vasoconstriction. In the late stages the difference was reversed as a result of either injury to the thermal centres or local accumulation of metabolites, visceral vasoconstriction failed, leading to a fall in blood pressure, decreased cutaneous circulation, and death. These results indicated that the circulatory collapse caused by pyrexia was peripheral rather than cardiac.

Another series of experiments was concerned with the effects of heat pyrexia on cardiac reserve. Rats were anaesthetized, and given sudden massive intravenous infusions of saline. The venous pressure rose but quickly fell to normal again. In rats not exposed to heat it remained normal, but in rats heated to 42–43°C there was a secondary rise in venous pressure, followed by a fall in arterial pressure, and death. At autopsy, pulmonary oedema was found. From this it was concluded that heat pyrexia caused impairment of the cardiac reserve, and that in patients with pre-existing cardiac disease it might be expected that heat stroke might lead to cardiac rather than peripheral failure. In mice exposed to heat it was found that moderate doses of saline given intraperitoneally increased the duration of survival. Larger and smaller doses were ineffective. Experiments with digitals were inconclusive.

The effectiveness of treatment was investigated in rats and mice. The animals were heated to the point of coma, and then cooled. In rats, the fall in body temperature was followed by means of a thermometer inserted in the large intestine, in mice the efficiency of the treatment was estimated by the number of mice surviving. It was found that immersion in ice-water produced more rapid cooling and a higher survival rate than cooling by wetting and fanning. Recommendations for treatment are given, based on these experimental findings. [It is a pity that the limitations of animal experiments prevented the authors from extending their rigorous and careful work to the third problem—"why do the patients stop sweating?" Circulatory collapse seems to be a secondary effect of heat stroke, not a part of the condition *per se*, it is an uncommon complication in fit and young subjects, e.g. in Service personnel developing heat stroke in India or Iraq. In these patients, treatment by wetting and fanning in a cool room has proved effective, even if it does not produce the most rapid cooling [this *Bulletin* 1945 v 42 143]. Ice-water is seldom available in large quantities in the desert. In practice the most important gap in our knowledge is not of treatment, but of prevention. This gap cannot be filled until more is known about why sweating suddenly stops.]

BALMANN C & GAILLARD Blanche D E. De practische betekenis van de functiebepaling der bloed-Eigenschappen bij neurologische patiënten in de tropen [Estimation of Plasma Permeability of the Choroidal Barrier in Tropical Neurology] *Nederl Tijdschr v Geneesk* 1948 Mar 6, v 92 (1) No. 10 688-93. English summary (4 lines)

Discussion of the significance of the different composition of blood plasma and cerebrospinal fluid indicates that it is a physical and physiological phenomenon. The present article deals with this point and goes on to an argument which would explain "Tropical Headache" largely a hemicrania, as being due to increased function of the choroidal vascular plexus. The result of exposure to tropical conditions is given as increased permeability of the capillaries and an altered inorganic composition with increased tension of the cerebrospinal fluid. Estimation of the plasma quotient, or blood-cerebrospinal fluid ratio which normally for the Walter bromide test, should be 2.9 to 3.3 is considered to support the contention and, therefore, to indicate therapy directed towards the regulation of this functional disturbance. The test is described in detail and three tables furnish the data regarding patients tested, who were soldiers present in the tropics for only a short time. [The Walter bromide test is based on the fact that the ratio of the amount of bromide in the blood and cerebrospinal fluid is constant in normal persons, but may vary in those suffering from mental disorder.]

DAVIES J N P. Pathology of Central African Natives. Mulago Hospital Post Mortem Studies V *East African Med J* 1947 Dec. v 24 No. 12 437-49 (23 refs.)

Part V of this series deals with spirochaetal diseases in Uganda. Most attention is given to syphilis and yaws, but rat bite fever has been seen. Tick borne relapsing fever (*Ornithodoros moubili*) has long been a scourge in Uganda, but autopsy findings are not diagnostic and spiruochetes tend to disappear soon after death. Vincent's infections are frequent as primary and secondary invaders. Their relation to tropical ulcer will be discussed in a later paper. Cancerum oris is attributed to this infection.

The incidence and characters of syphilis recorded by LAMBLIN (1929) and KEANE (1917) are contrasted with those occurring at present. The incidence is now lower and congenital syphilis is rare. Secondary syphilis is said to be infrequent (this appears to be a misinterpretation from a paper (*Brit Med J*, 1947 Jan. 18 68) see also this *Bulletin* 1947 v 44 527) by the reviewer. Tertiary lesions and neuro-syphilis are common. For the latter statement the author quotes from an unpublished thesis, so also for severe and often phagedenic chancres. Forty years ago the incidence was otherwise. It is suggested that the disease described by Lambkin & Keane was yaws not syphilis despite their reports of much congenital syphilis. The author has been informed that one doctor sees a lot of yaws—in the country round Kampala. (No mention is made of endemic syphilis, such as has been reported from other countries.)

In 2,994 autopsies (1931-1946) syphilitic lesions were recorded in 11.3 per cent (336). 90 per cent. were men. In 77 per cent. of these syphilis was the main cause of death. Aortitis accounted for 61.7 per cent. (207) neuro-syphilis, 44.5 per cent. (154) aortitis with neurosyphilis 13 per cent. (57) gummata, 7.6 per cent. (26) (figures and totals do not tally). The findings in 1946 were similar. Aortic aneurysm was present in over half of the cases of aortitis in 1946. In 190 autopsies on neurosyphilitics 563 were found to be

G P I, 38 meningovascular, 5 pachymeningitis haemorrhagica and 3 transverse myelitis (in 48 there were insufficient data) The age at death for aortitis and neurosyphilis was about 40 years Neurosyphilis is quoted as constituting 0.4 per cent of all admissions to Mulago, which includes a Mental Hospital. Tabes is rare Microscopically the changes in neurosyphilis of the brain are the same as those seen in Europeans Ghomata are more frequent than intracranial gummata. In other tissues, diffuse syphilitic fibrosis and gummatous lymphadenitis were not observed

[The author strays far from his title and wanders upon rather uncertain territory]

FISHER, A C, FISHER, MONICA M & LENDRUM, A C **Tropical Primary Phlebitis.**
J Path & Bact. 1947, July, v 59, No 3, 405-15, 6 figs on 3 pls

This paper records a continuation of the studies first reported by FISHER [this *Bulletin*, 1942, v 39 199], and reference is made in it to the paper by MANSON-BAHR and CHARTERS [*ibid*, 1946, v 43, 1186] and to that by GELFAND [*ibid*, 1947, v 44, 539] The authors think that the conditions described by these other workers and themselves are the same Fisher writes from the Roan Antelope Hospital Service, Luanshya, Northern Rhodesia, Lendrum from the Department of Pathology the University and Western Infirmary, Glasgow

They have now seen 71 cases of tropical primary phlebitis (as they now name the disease), of these, 7 were fatal Two main types are defined phlebitis major (68 cases) in which large veins are involved, and in which there is a general reaction, with fever, and phlebitis minor, which is a lesion of small veins, easily diagnosed when the veins involved are superficial, in which general symptoms are slight In the severe form the onset is usually sudden, with local pain, tenderness and swelling over the affected vein, and muscular spasm There is venous engorgement distal to the inflamed area, and secondary thrombosis occurs In milder cases there is no residual oedema (after subsidence of the acute condition in 2-3 weeks) but in severe cases the limb may be left in a condition of permanent oedema The authors think that some of the cases of stiff neck reported by Manson-Bahr and Charters may have been due to deep-seated phlebitis No suppuration or embolus formation has been noticed

Of the 92 lesions reported, 34 were of the femoral vein, 8 of the popliteal, 16 of the axillary, and 7 of the subclavian vein, but other veins, including the internal (8) and external (6) jugular veins and the portal system (5), may also be involved The disease may be fatal when cerebral sinuses or important veins are diseased and since these veins may become involved after onset in a superficial vein, the prognosis should always be guarded

Sulphonamides were of no apparent benefit in treatment, but the use of anticoagulants would seem to be worth trial Illustrative cases are described

The second part of the paper is devoted to a discussion of the aetiology and pathology of the condition Blood culture was negative in 11 of the 12 cases in which it was tried in the other one *Streptococcus viridans* was isolated, but this is not thought to be a significant finding Kahn, Widal and Weil-Felix tests were not found to be relevant, malaria, the sickling trait and helminthic infection were not important There was slight leucocytosis with (sometimes) moderate relative lymphocytosis

Tissues were available for microscopic examination from several patients, and the jugular vein of one was examined in detail and under good conditions In this there was a remarkable disruption of the normal tissues of the media and intima, with newly formed capillaries set in a loose oedematous ground-work in which there were large cells of uncertain nature and neutrophils The endothelial cells showed evidence of urgent proliferation, there were other

large cells (reacting polyblasts) and in these there were cytoplasmic inclusion bodies which were clearly demonstrated when stained by the phloxin-tartrazine method (described by LANDRUM on p. 399 of the same issue of the *Journal*). The point is made that fixation of tissues in formalin is rarely satisfactory for this purpose and that formal-sublimate (1 part commercial formalin to 9 parts saturated aqueous mercuric chloride) should be used for 10-14 days.

The detailed description of the lesions should be read in the original. The authors point out that they may be very localized, and consequently easily missed. The changes are quite unlike those associated with bacterial infection and the presence of inclusion bodies raises the question of virus infection though no virus has yet been recovered. This seems to be a newly discovered disease which occurs only sporadically in Rhodesia (though the outbreak described by Manson Bahr and Charters elsewhere in East Africa was more in the form of an epidemic). It may be more widespread in Africa than is at present realized, and there may be cases in which obscure symptoms (for instance splenic softening or splenic abscess) are in fact due to the same cause. The method of spread is not known.

CHARTERS, L. D. & MANSON BAH, P. E. C. Symmetrical Gangrene in the African. [Correspondence.] *Brit Med J* 1948, Mar 13 520

GELFAND (see this *Bulletin* 1947 v 44 837) described 6 cases of symmetrical gangrene of the feet, in S Rhodesia. Charters and Manson-Bahr suggest that the aetiology of this condition may have been similar to that of thrombophlebitis (see this *Bulletin* 1948, v 45, 1186). There is some similarity of early symptoms between Gelfand's cases and thrombophlebitis, and gangrene due to arterial thrombosis was seen in two of their patients in whom the first signs were of phlebitis.

Charles H. Steele

HARRIS E. J. LEWIS A. A. G. WARING J. W. B. & DOWLING, E. J. Melioidosis treated with Sulphonamides and Penicillin. *Lancet* 1948, Mar 6 363-6 3 figs.

The authors describe five cases of melioidosis which occurred in West African soldiers at various places between Freetown and Rangoon, Burma, during 1948. Two of the cases, in which there were multiple abscesses in the liver, spleen or lungs, proved fatal in spite of treatment of one patient with sulphathiazole and of the other with various sulphonamide drugs and penicillin. It is considered unlikely that cases with multiple abscesses in the internal organs will respond to any known form of treatment.

Of the other three cases one had superficial abscesses and two had infections involving the lungs. All recovered after combined treatment with sulphonamides and penicillin. It is known that *P. aeruginosa* is not sensitive to ordinary concentrations of penicillin but the strain from one of the cases now reported was inhibited *in vitro* by 6.0 units per ml. The treatment now recommended is to give sulphamerazine 2 gm. every 4 hours for at least 10 days and to incise all accessible abscesses or to aspirate them and instil penicillin locally. Where there is a rise in agglutinin titre serum may be used.

The suggestion that colonial roughness is associated with melioidosis was supported by the observation that the strain from the three patients who recovered were noticeably less rough than the others.

The report also indicates that an agglutinin titre of 1/80 is likely to be significant and a titre of 1/100 almost certain diagnostic of melioidosis.

ENTOMOLOGY AND INSECTICIDES GENERAL

MUESEBECK, C F W Common Names of Insects of Medical Importance approved by the American Association of Economic Entomologists *Mosquito News* 1947, June, v 7, No 2, 70-72

This is a short list of insects, classified in two forms 1 By the common names with the scientific names appended (e.g., American dog tick—*Dermacentor andersoni*), and 2 *Vice versa*

Its importance is that the names are approved, but some of them are only of local use For instance the "common malaria mosquito" is *A. quadrimaculatus* Charles Wilcocks

DUBIN I N, REESE, J D & SEAMANS, LOIS A Attempt to produce Protection against Mosquitoes by Active Immunization *J Immunology* 1948, Mar., v 58, No 3, 293-7 [13 refs]

In this experiment the attempt to protect rabbits against mosquitoes by vaccination with mosquito antigen proved unsuccessful Moreover, the rabbits so inoculated with a crude suspension of mosquitoes became sensitized to mosquito bites in contrast to the normal non-sensitive rabbits The sensitized rabbits showed large indurated reddened papules at the site of the bites These cutaneous reactions began in about 30 minutes and reached their maximum size at about 5 hours

Attempts at desensitization of the sensitive animals were unsuccessful under conditions of the present experiment Passive transfer of the sensitivity to normal animals was also tried but without success

MOSQUITO CONTROL Suva, Fiji Revised 1947 43 pp, 39 figs [11 refs]
Training Manual, including Section on the Organization of the Filariasis Campaign in Fiji [AMOS, D W, Senior Mosquito Inspector]

This short pamphlet was written by a retired successful business man who became a Mosquito Inspector when manpower was short during the war, and who developed great interest in, and aptitude for, entomological work. It is written as a guide for field inspectors, the language is simple and clear, and there are many excellent line drawings of mosquito larvae and adults showing the important anatomical features The mosquitoes concerned are those found in Fiji

The pamphlet includes a key for the identification of larvae notes on adults and their habits (various species of *Aedes*, *Culex* and others are described) a section on mosquitoes as vectors of disease, and a section on filariasis in which the author gives his views on methods of control

The author has studied his material at first hand, and has consulted recognized authorities The pamphlet will undoubtedly be useful, and indeed, has already proved its value the comments of Dr McGusty and Dr Buchanan in their forewords leave no doubt on that point

JAYWICKREME, S. H. & NILES, W. J. Rearing of *Trombicula acuminatulus* Walch. *Nature* 1947 Oct., 5 578.

The authors describe with much useful detail, the method by which they have reared four generations of this mite.

They generally feed nymphs or adults on eggs of mosquitoes, but have seen them feed on small freshly-killed insects of several sorts. Eggs are laid in damp cellulose wadding. They hatch in ten to twelve days. The larvae are fed on white mice which must be immobilized until the larvae have attached themselves. The engorged larvae drop off from the third to the seventh day. KOMLS G. M. *Ixodes radfordi*, a New Species of Tick from Rats in Eastern India (Acarina: Ixodidae). *J. Parasitology* 1947 Dec. v 33 No. 6, 497-8, 1 fig.

WHECUP C. B. WHITE, W. C. & MIDDICK, V. S. Airplane Spraying with DDT for Control of Salt-Marsh Mosquito Larvae. *Lifeskills News* 1947 Sept. v 7 No. 3 103-8.

"Large-scale applications of DDT sprays from airplanes as pre-flooding treatments gave no control of salt-marsh mosquito larvae in 1945.

Direct application of DDT sprays by airplanes is a feasible method of controlling salt-marsh mosquito larvae. The treatments must be applied before pupation commences and sufficient material should be applied so that it penetrates the vegetative cover. A minimum effective dosage was 0.4 pound of DDT per acre. More satisfactory control was secured from the application of 0.4 pound of DDT per acre. At this dosage a sufficient amount of DDT to control *Aedes* larvae penetrated all except the tallest and densest vegetation.

BURT D. H. D.D.T. in S.E.A.C. *J. Roy. Soc. Med. Serv.* 1947 July 33 No. 2, 197-200, 1 chart

GUNTHER, F. A. Thermal Decomposition of DDT and Benzene Hexachloride Mixtures. *J. Econom. Entom.* 1947 Dec., v 40 No. 6, 874-7 (10 refs.)

"Thus it becomes apparent that benzene hexachloride in any of the forms studied has a pronounced deleterious effect upon the thermal stability of DDT in admixture. In all probability the hexachloride preparations contained minute traces of iron or other catalyzing materials which incited this response. Benzene hexachloride and its alpha, beta, gamma, and delta isomers appear to be quite stable thermally to 120°C. even with added ferric iron in contradistinction to the behavior of DDT under similar experimental conditions.

REPORTS, SURVEYS AND MISCELLANEOUS PAPERS

CONGO BELGE Rapport sur l'Hygiène Publique au Congo Belge pendant l'année 1946 [Report on the Public Health in the Belgian Congo during 1946] [LAMBRICHTS, G P] 202 mimeographed pp, 2 charts & 2 folding maps

This report, in addition to covering the medical activities of the Belgian Congo during the year 1946, contains some observations relating to 1945, as publication of the report for the latter year was delayed

Staff shortage was acute during 1946, since as many members as possible were allowed to take post-war leave, and replacements were difficult to obtain The report contains the usual detailed statistical account of the work of government, missionary and philanthropic bodies Comprehensive figures are given for the incidence of the common infectious diseases, and for attendances, treatments and epidemiological data In many cases, comparative figures are given for the preceding ten to fifteen years

The report contains a vast amount of informative matter, and gives a very full indication of the extent and nature of the medical problems encountered and of the facilities available for dealing with them

H J O'D Burke-Gaffney

BULL INST HYG MAROC 1945, v 5, 97-189, 9 charts Rapport sur l'activité des Services de la Direction de la Santé Publique et de la Famille pendant l'année 1945 [Public Health Activities during 1945 in Morocco]

The Directorate of Public Health of Morocco encountered special difficulties in 1945 More than half its personnel was engaged on war duties, unprecedented scarcity, due to deficient rain, coincided with a severe epidemic of relapsing fever which spread from Tunisia and Algeria. There was also an outbreak of typhus fever and small outbreaks of plague in the Casablanca region Mild smallpox was also prevalent throughout the territory Malaria, on the other hand, was less prevalent than usual, thanks to deficient rain

Temporary hospital accommodation had to be created The total number of hospital admissions was 96,084 "fevers" were responsible for 59.5 per cent of these admissions Among these there were 1,520 cases of relapsing fever, 149 typhus fever, 275 smallpox, and malaria 6,510 cases, mostly mild Malnutrition contributed to high case-mortality rates

The death rates for the year in the 18 municipalities were Mussulmans 36, Jews 19.8, Europeans 10 per thousand

Registered cases of smallpox numbered 2,618, of which 36 were among Europeans, vaccinations numbered 1,667,898 Diphtheria prevalence is decreasing, only 203 cases and 16 deaths were recorded There were 51,975 declared cases of amoebic dysentery and 4,175 cases of bacillary dysentery These figures give an exaggerated idea of the importance of the outbreak During 1945, the influx of very large numbers of ill-nourished destitute persons, many of whom were suffering from diarrhoea with blood and mucus, was on such a scale as to preclude the possibility of laboratory investigation in most cases

Before 1945, no large-scale epidemic of louse-borne relapsing fever had ever been experienced in Morocco Cases of the African (tick-borne) form of the disease are reported from time to time, chiefly in the region of Port-Lyautey The Health Service was alive to the dangers of the introduction of epidemic relapsing fever from Algeria, but, unfortunately, adequate supplies of DDT were not available till the end of July, when the epidemic was near its height The

first cases were recognized in January and the incidence curve rose steadily during the subsequent six months. For the country as a whole the acme of the epidemic was reached in the early weeks of 1948. In any given locality however the epidemic was not so long drawn out—it usually reached its height in 3 or 4 months and then rapidly subsided. (By August 1948 the disease had disappeared from Morocco.) During 1945 28,300 cases of relapsing fever were notified. The case-mortality rate varied from place to place and from season to season, between 1.8 and 8.9 per cent.

Typhus fever notifications were 8,168—the disease was widespread. The case-mortality rate for natives of Morocco 13.7 per cent., was higher than usual owing to the undernourished condition of the population at risk.

There were 828 cases of plague.

Norman White

DOCUMENT ALGERIENS. Sér. Soc. 1948, Sept. 15 No. 9 13 pp. L'œuvre de l'Institut Pasteur en Algérie [SERRANT Ed., Director] [The Work of the Pasteur Institute in Algeria.]

A review of work undertaken since 1900

GUYANE FRANÇAISE. Rapport sur le fonctionnement technique de l'Institut Pasteur de la Guyane Française et du Territoire de l'Inini pendant l'année 1946 [FLOCH, H., Director]. 'Report of the Pasteur Institute of French Guiana and Inini for the Year 1946.' Publication No 151 168 pp. 1947 Cayenn

The amount of work done by the Director of this Institute and his assistants, during 1946 was remarkable both for scope and quantity, and in the Report a very detailed account is presented. The tables of pathological and other scientific examinations performed occupy some 30 pages, and include statements of organisms found or cultivated and of insects and other creatures identified.

In section 4 there are essays, of different lengths, in which current medical problems are discussed—leprosy and its diagnosis and treatment, tuberculosis, venereal diseases, yaws, leishmaniasis, brucellosis, meningitis, beriberi (of which there was an outbreak in 1945), cancer, and other conditions. Malaria is discussed in the following section, and an account is given of a series of investigations on spleen rates (8-10 per cent.), parasite rates (3-46 per cent.) *P. falciparum* being by far the most common and other lodgers. *Anopheles aquasalis* and *A. darlingi* are the most common anophelines, but only the latter has been found infected in nature though *A. aquasalis* can be infected experimentally. In this section also there is an account of the preparation of diphtheria antitoxin (Ramon) and its use in a small outbreak, a detailed statement of the leprosy position and the measures taken to deal with it, and statement of the examinations performed in relation to the dysenteries and diseases of the typhoid group.

Examination for intestinal parasites (especially for flukes, hookworms and *Trichuris*) blood-group work, veterinary work, botanical work and entomological work (reported in great detail) complete this section. The Report concludes with a statement of vaccines sera, etc., prepared and of vaccinations performed.

The Report is long and detailed, and there is some repetition—but within its limits (as the account of an institute dealing largely with infective or parasitic diseases) it gives a comprehensive picture of conditions in French Guiana.

Charles H. Wood

It is less a book for the lay worker than for the doctor and, in fact, a hope is expressed that it may be useful for those working for higher degrees in Tropical Medicine.

There is very little to criticise and much to praise. One would perhaps have liked a little stronger warning about the use of carbon tetrachloride. One will look for results of the sulphone drugs in leprosy as they begin to be used in South Africa. A résumé of the use of the antibiotics might be helpful.

There are very few misprints, but there are a few mis-spellings such as "Chrysopsis" "carbasones" for carbarsone, "pharynoderma" and "S. stercorales".

The cure of the sick African is rightly stated to lie in the training of African doctors in their own country. But this will take a long time and the economic development of the continent is being so accelerated that less highly trained men may have to be used for generations. Let us hope that a worthy Native Medical School may before long be set up in the Rhodesias.

C. C. Chesterman

MITCHELL, John P. (C.B.E. M.D.). *Anatomy and Physiology and Causes of Disease*, 2nd Edition. pp. xvi+228 87 figs. & 2 diagrams. Baillière's Elementary Tropical Handbooks. 1943. London Baillière Tindall & Cox, 7 & 8 Henrietta Street Covent Garden, W.C.2. [3s.]

This is the second edition of one of the Elementary Tropical Handbooks for nurses and orderlies which are becoming as familiar in the tropics as the publisher's "Aids" series are in Britain.

The elementary principles of anatomy and physiology are simply stated and adequately illustrated under headings which correspond with the various systems of the body.

The knowledge thus imparted is reinforced in each chapter by the inclusion of suggestions for a series of simple demonstrations on the living subject, the cadaver or on available animals etc. The whole is related to clinical and ward work by the introduction of notes on the common diseases of the organs or tissues described.

Thus, theory, demonstration and application go hand in hand throughout the book and the student is kept close to demonstrable facts and familiar realities.

In the pathological section one misses among the various causes of disease any reference to congenital conditions, degenerations and neoplasms (except under unknown causes). The life history of the malaria parasite needs bringing up to date and the rickettsiae might find a humble place between the viruses and the bacteria in view of the prevalence of some sort of typhus fever in so many parts of the tropics.

The author wisely insists in his preface that this book is meant to be used by those who are receiving tuition. All those engaged in teaching will find it an invaluable aid.

The only misspelling noticed was *Onchocerca* for *Onchocerc* on p. 13 and in the index. This edition contains new sections dealing with blood pressure shock and blood transfusion. Otherwise only minor changes have been made in the revised text.

The sulphone of choice in Lepromatous Leprosy

First reports on the value of 'Sulphetrone' in the treatment of lepromatous leprosy, were confirmed at the Fifth International Congress of Leprosy, Havana, when this new product was referred to as the sulphone of choice

Trials show that the administration of 3 to 6 gm daily produces a satisfactory clinical response in the majority of lepromatous cases 'Sulphetrone' is issued as 'Tabloid' brand compressed products, each containing 0.5 gm, in bottles of 500

'SULPHETRONE'

TETRASODIUM 4,4-BIS (γ-PHENYLPROPYLAMINO)
DIPHENYLSULPHONE • γ • γ TETRASULPHONATE

WHERE

immediate response

IS VITAL

Where the blood picture in macrocytic anaemias demands immediate action 'FOLVITE' (Folic Acid, Lederle) can be relied upon to give a dramatic response. Within a few days small oral doses of 'FOLVITE' have produced a marked improvement in the blood picture and clinical condition in cases of pernicious anaemia, sprue, nutritional and gestational macrocytic anaemias.

The Lederle Laboratories, who originally isolated and synthesised folic acid, offer the profession the experience of their medical staff.

THE CHEMOTHERAPY OF RICKETTSIAL INFECTIONS

By G M FINDLAY, C.B.E., M.D., D.Sc., F.R.C.P.

Before the War of 1939-1945 there was no known drug which had any effect on rickettsial infections. Now a number of compounds of widely different chemical constitution have been found to inhibit the growth of rickettsiae in chick embryos or to influence rickettsial disease in mice. Only *para*-aminobenzoic acid and chloromycetin are known to have an ameliorative action on rickettsial infections in man, but acridine derivatives, streptomycin, certain sulphonamide compounds and methylene blue all have a rickettsiacidal action in animals.

Not all species of rickettsiae are equally susceptible to rickettsiacidal agents. *Rickettsia burneti*, the causal agent of Q fever, for instance, is unaffected by penicillin or sulphonamides (SPICKNALL *et al* 1947).

There is still some doubt as to the best method of determining anti-rickettsial action. Three techniques are possible—(1) the injection of rickettsiae and drug into developing hens' eggs, (2) intranasal instillation of rickettsiae and intraperitoneal injection of the drug in mice counting the lung lesions, (3) intradermal inoculation into rabbits of a mixture of rickettsiae and drug after preliminary incubation. It is probable that, as in the case of malaria, each compound should be tested in more than one host, in this case in mice or rabbits and in the developing chick embryo.

In chemotherapeutic studies the following agents have been investigated—

(i) *para*-Aminobenzoic Acid (PABA)

The effectiveness of *p*-aminobenzoic acid (PABA) in mice infected with murine typhus was first demonstrated by SNYDER *et al* (1942), they employed it on finding that sulphonamides appear to stimulate the growth of rickettsiae, since PABA is a known sulphonamide antagonist. Evidence of the action of PABA in a considerable number of rickettsial infections was subsequently obtained in many laboratories. In the yolk sac of developing chick embryos PABA or its sodium salt inhibits the multiplication of *Rickettsia mooseri* (GREIFF *et al* 1944, HAMILTON *et al* 1945), *R. prowazeki* (HAMILTON *et al* 1945, HAMILTON 1945) and *R. orientalis* (SNYDER *et al* 1947), *R. rickettsi* (HAMILTON 1945) the susceptibility of *R. quintana*, *R. burneti* and *R. akari* is not yet known. In experimental rickettsial infections the mortality in white mice (SNYDER *et al* 1942), gerbils (SNYDER and ZARAFONETIS 1945, MURRAY *et al* 1945, ZARAFONETIS *et al* 1946) cotton rats (SNYDER *et al* 1947), and guinea-pigs (ANIGSTEIN and BADER 1945, 1946), is considerably reduced by PABA. *et*

In 1944 YKONOMAS *et al.* obtained a favourable therapeutic effect in patients in the first week of epidemic typhus in Egypt. The figures obtained in this study have been examined statistically by SYLVAN *et al.* (1947). 20 patients were treated with PABA and 19 alternate cases with those treated, were used as controls. Treated patients had shorter fever, fewer complications and a lower mortality rate than the untreated controls. These differences were significant. In the treated group, there was a significant correlation between the final score (the number of days of fever plus the number of complications) and the duration of the illness before therapy was instituted. SYLVAN *et al.* (1947) also report the results of treating 60 patients suffering from typhus in the Dachau Concentration Camp in Germany in May 1945. Analysis of the results shows that there were statistically significant differences between PABA-treated and untreated patients as regards duration of fever, incidence of complications and mortality. All the evidence suggests that treatment begun early in the first week of illness is more effective than treatment begun late in the same week. In Northern Nigeria, during an epidemic of typhus, MONTGOMERY and BUDDEX (1947) treated six of the worst cases with PABA, all recovered whereas the mortality rate in the outbreak as a whole was 25 per cent.

SMITH (1946) reported the use of PABA in 29 cases of murine typhus. LEVY and ARNOLD (1946) in 6 and DIAZ RIVERA *et al.* (1946) in 4 cases, all with apparently good results. SMITH carefully compared his results with those in 29 controls. Of the treated cases only 7 had fever for 12 days or more whereas in 22 of 29 controls the temperature was above normal for at least 1 day. The average duration of fever in the two groups was 10.3 and 13.2 days respectively. DIAZ RIVERA *et al.* (1946) gave total doses of 102 to 136 gm., a dose of 2 gm. in 25 ml. of 5 per cent. sodium bicarbonate solution was given every 4 hours. Subjective improvement began in from 4 to 48 hours after the beginning of treatment.

One patient suffering from Rocky Mountain spotted fever was successfully treated with PABA by ROSE *et al.* (1945). MAKOVNEY *et al.* (1946) similarly treated one case. FLINX *et al.* (1946) obtained good results in nine out of ten patients. Blood levels of 30 to 60 mgm. per 100 ml. were necessary for success. TICHENOR *et al.* (1947) used PABA in 8 children suffering from Rocky Mountain spotted fever. All recovered but in the previous 30 patients who had not received specific treatment only 7 had died. The most striking result was in a patient who was given the drug on the third day of illness. The daily dose was 0.3 gm. per kilo of body weight in 24 hours divided into 3 hourly doses. RAVENEL (1947) reported five cases in children and adolescents from 3 to 17 years old. The following case is typical of those treated —

A delirious wasted boy 17 years old suffered from a haemorrhagic rash together with conjunctivitis, palatal exanthema and serotul oedema. Para-aminobenzoic acid, 2.5 gm. in 5 ml. (a 5%) solution of sodium bicarbonate, was given orally every two hours for the first two days. At the end of this time the blood concentration of PABA was only 4 mgm. per 100 ml. The dose was then increased to 5 gm. every two hours in 50 ml. of solution. After 24 hours the blood level had risen to 18 mgm. and a day later to 32 mgm. per 100 ml. The temperature dropped sharply on the fifth day and was normal on the sixth when the rash faded rapidly, the mind cleared and the boy was almost well. The other four cases improved equally rapidly.

WILKS and BOCKHE (1946) in treating a girl aged 4½ years with PABA gave 2 gm. in 10 ml. of 5 per cent. sodium bicarbonate solution with 10 ml. of grape juice. This dose was repeated every 4 hours for 8 days. Grape juice helped the patient to retain the drug, which had previously been vomited.

Successful results in the treatment of 18 cases of scrub typhus were recorded from Burma by TIERNEY (1946)

There is now general agreement that, if success is to be obtained with PABA, certain conditions must be fulfilled. Good results from PABA therapy are to be expected in epidemic, murine and scrub typhus and the same is probably true of other forms of typhus, but only when treatment is begun during the first eight days of the disease. Thus, if there is clinical or epidemiological evidence to point to rickettsiae as the cause of a particular disease, it is as well to begin PABA treatment while waiting for the diagnosis to be established by laboratory tests, provided that certain contraindications are not present.

Precisely what is the optimum concentration of PABA in all rickettsial infections is at present unknown. Some of the PABA in the body is changed into *p*-aminohippuric acid, which is inert against *R. prowazeki*, *R. mooseri* and *R. orientalis* (SNYDER *et al* 1947) in experimental infections and probably against other rickettsial infections as well. Analyses made with Mirick's soil bacillus (MIRICK 1943) suggest that about 80 per cent of all diazotizable substances in the serum is free PABA when the total concentration in the serum is 15 to 20 mgm per 100 ml. In developing hens' eggs the minimum concentration of PABA required to achieve inhibition of multiplication is approximately 5 mgm per 100 ml for *R. prowazeki* and *R. mooseri*, but with *R. orientalis* it is at least 35 mgm per 100 ml. SNYDER *et al* (1947) therefore recommend that sufficient PABA should be given to attain promptly and to maintain for the entire period of the therapy a blood concentration, as free diazotizable substance measured against a standard of PABA, of 10 to 20 mgm per 100 ml for patients with typhus and of 35 to 40 mgm per 100 ml for patients with scrub typhus or Rocky Mountain spotted fever. Since PABA is rapidly excreted in the urine, the drug must be given at frequent, regular intervals during the day and night. The initial dose is roughly 0.05 gm per pound of body weight (0.11 gm per kilo) or 8 gm for a patient weighing 160 pounds (72.5 kgm). This is followed by a dose of 1 to 3 gm every two hours day and night throughout the course of treatment. The PABA administered should be chemically pure, odourless and almost colourless in powder form. In solution a faint brown colour is present. At least equimolar amounts of sodium bicarbonate should be given with each dose of the free acid (12.5 ml of a 5 per cent solution of sodium bicarbonate for each gramme of PABA). The amount of bicarbonate must be varied so as to keep the urine neutral or alkaline. For convenience, the powder (PABA) is mixed with a 5 per cent solution of sodium bicarbonate at the bedside immediately before each dose. After taking the dose the patient should be given 100 ml or more of water to drink.

SNYDER *et al* (1947) used a 10 per cent solution of the sodium salt of *p*-aminobenzoic acid, adjusted to a pH of 7.0, for the treatment of a patient with typhus contracted in the laboratory. A 10 per cent solution of the salt can be made up in bulk and stored in the cold for some days. No bicarbonate solution is necessary unless the urine becomes acid.

It is imperative to estimate the blood concentration at frequent intervals, particularly in patients with azotaemia and where appreciable fluctuations in fluid intake and urinary output occur from day to day. If possible, the blood concentration should be estimated every four hours during the first 24 hours, immediately before a dose of PABA. Except when renal insufficiency is present, estimations may then be limited to once in every twenty-four hours.

Intramuscular administration (the solution being sterilized by filtration through a Seitz filter) is unsatisfactory, but intravenous drip injection may be of value in patients who are unable to swallow. The rate of flow is adjusted to permit the infusion of from 25 to 30 gm of the drug in the course of 24 hours.

It is advisable to continue treatment for at least 48 hours after the temperature has become normal, otherwise both in typhus and scrub typhus the temperature may rise and in the latter condition the adenopathy may recur (TURNER 1946).

If the urine is acid there may be a precipitation of crystals of PABA in the kidney tubules. The pH of the urine should be tested with litmus paper at least twice daily as long as patients have measurable concentrations of the drug in the blood. Usually it is only in cases of azotaemia that more than 13 to 20 ml. of a 5 per cent. solution of sodium bicarbonate for each gramme of PABA is necessary to bring the pH of the urine to 7.0 or higher. Signs of renal involvement, such as azotaemia or haematuria, are less frequent and less severe in the treated than in untreated typhus patients. The urine of some patients under treatment with PABA contains reducing substance of unknown significance.

p-aminobenzoic acid is not without toxicity. In rats a single dose of 10 gm. per kilo of body weight kills 90 per cent. of immature and 45 per cent. of adult rats. The main pathological change found by ROBIN *et al.* (1947) was hyperaemia of the distal segment of the stomach. PABA added to the diet for 6 months to the extent of 4 per cent. produced no lesions in rats.

In patients, one of the main toxic symptoms is nausea with occasional vomiting. It is, however, rarely necessary to interrupt treatment for this cause and 250 gm have been given without evil effects. Leucopenia may be seen in some typhus patients treated with PABA. White cell counts should therefore be performed on every patient daily from the start of therapy until three or four days after its cessation. When the total white count falls below 3,000 per cmm. or the percentage of polymorphonuclear leucocytes below 45 per cent. no further treatment should be given. In each individual case however it is necessary to determine whether a falling leucocyte count is more serious than the withdrawal of the inhibiting effect of PABA on the rickettsiae.

There is some evidence that PABA slightly decreases the carbon dioxide combining power of the serum possibly also it slightly and transiently impairs liver function as shown by prothrombin and cephalin-flocculation tests.

If PABA crystals appear in the urine the administration of the drug should be stopped at once. In patients who are too weak to swallow properly care must be taken in giving PABA by mouth. Aspiration of PABA may be followed by severe tracheo-bronchitis. The presence of renal insufficiency before treatment or its appearance during the course of therapy is not a reason for withholding or discontinuing PABA, provided that the blood concentration is determined frequently that adjustments in dosage are made accordingly, and that the urine is kept neutral or alkaline in reaction.

PABA therapy is probably not indicated for typhus patients under 40 years of age if they have been adequately vaccinated against the disease (ECKE *et al.* 1945) unless they show signs of developing a very severe infection. In cases of suspected scrub typhus PABA should be administered irrespective of any history of previous vaccination since there is as yet no satisfactory evidence that vaccines prepared from *R. orientalis* have any beneficial effect on the course of the disease in human beings.

SXTEDER *et al.* (1947) found no lesions which could be regarded as evidence of poisoning with the drug in four patients who died despite adequate doses of PABA. One fatal case showed an unexplained nephrosis. Possibly PABA might be more toxic in those with severely damaged livers.

Secondary bacterial infections are not uncommon in patients with typhus. The presence of such infections does not contraindicate PABA therapy but sulphonamides are contraindicated since their action is inhibited by PABA. They should therefore never be given during the acute febrile phase of a

rickettsial disease under PABA treatment or while measurable amounts of PABA are still present in the blood. Penicillin is obviously the drug of choice where the secondary bacterial organisms are susceptible to it. Penicillin may be used to supplement, but not to replace, PABA.

In view of its use in rickettsial infections and also because of the relationship of this compound to sulphonamide action, the pharmacology of PABA has received considerable study. Earlier investigations are reviewed by LUSBACHER (1944). According to BLOOMBERG (1946), PABA is rapidly absorbed within 8 hours from the intestine, chiefly the small intestine, but only about 50 per cent of an oral dose is absorbed. LUSTIG *et al* (1944), using PABA in which the nitrogen was replaced by the isotope N^{15} , found that there was no utilization or storage of the labelled nitrogen. 82 per cent of the labelled compound was excreted 19 hours after an injection. When given by mouth PABA appears in the urine after 8 hours. Very little free PABA is present, most of it being converted to *p*-aminohippuric acid in the liver. Part of the *p*-aminohippuric acid is acetylated before excretion.

Very little is yet known of the mode of action of PABA on rickettsiae. However at least one variety of *Neurospora* is known which requires sulphanilamide for its growth. The growth-promoting action of sulphanilamide is inhibited by PABA. LICO and SOLOMONIDES (1947) have shown that PABA inhibits the growth of *Bacterium coli*. GREIFF and PRICKERTON (1948) think that PABA acts by increasing the oxygen uptake of typhus-infected eggs. Ortho and meta-aminobenzoic acid are not rickettsiastatic and do not increase oxygen uptake. BENIGNO (1947) believes that PABA depresses the body temperature so that rickettsiae cannot multiply. Methods of estimating *p*-aminobenzoic acid in the tissues have been devised by LEWIS (1942), KIRCH and BERGER (1943) and PENNINGTON (1946). Microbiological assay is the simplest method, the organism used being either *Lactobacillus arabinosus* 175 or preferably, according to Pennington, *Leuconostoc mesenteroides*. The extent of growth after 15 hours at 37°C is determined turbidimetrically (THOMPSON *et al* 1943).

(ii) Acridine Compounds

Claims have been made that mepacrine is of value in the treatment of louse-borne typhus either when it is given alone (VAN MEERENDONK 1942a) or with calcium (VAN MEERENDONK 1942b). These results have not been generally substantiated though in murine typhus ARDOVA (1945) believed that mepacrine is beneficial. FERRO-LUZZI and FERRO-LUZZI (1947) failed to detect any good results from mepacrine intravenously in louse-borne typhus. During the war FUSSENGER (1945) found that some acridine compounds were effective in

(I)

(II)

2,3-dimethoxy-6-nitro-9-(diethyl amino)-hydroxy-propylamine.
acridine dihydrochloride
The most active of
compounds were 2,3-dimethoxy-6-nitro-9-(diethyl amino)-hydroxy-
acridine dihydrochloride and 2,3-dimethoxy-6-nitro-9-(diethyl amino)-hydroxy-
acridine dihydrochloride.

arsenical salt of the former 1 molecule of nitroacridine being combined with 2 molecules of *p*-glycoyl aminophenylarsonic acid the arsenic being attached at nitrogen atoms (I) and (II). The previous information that rutinol is composed of two parts of nitroacridine with three parts of arsenic trioxide is incorrect.

No serious toxic manifestations attributable to these drugs were noted in a number of patients who received 2.5 gm. of nitroacridin 3582 or 4.0 gm. of rutinol given in divided doses over a period of two and a half days (FUSCHNER 1945 HOLLER and ZAJITSCHKE 1944 HOLLER 1944). The reported clinical effectiveness of these drugs in the treatment of epidemic typhus and trench fever (HOLLER and ZAJITSCHKE 1944 HOLLER 1944) requires further investigation.

SMADAL *et al* (1947a) confirmed the fact that nitroacridin 3582 and rutinol have a definite rickettsiastatic action on *Rickettsia prowazeki*, *R. mooseri*, *R. rickettsi* and *R. orientalis* in the developing chicken embryo. Acridavine (α -8-diamino-10-methyl acridinium chloride) was active when the dose was 0.4 mgm. per egg, close to the toxic level. Mepacrine dihydrochloride in amounts up to 2.0 mgm. per egg had no effect on *R. prowazeki* or *R. rickettsi*. 4.0 mgm. doses killed all embryos.

A comparatively simple compound prepared by ALBERT *et al*. (1945) 2-nitro-5-amino-acridine was found to be effective in doses of 0.2 mgm. per egg. This dose is as effective as 0.4 mgm. of nitroacridin 3582, but the former is more toxic as 0.4 to 0.5 mgm. doses killed one-half to two-thirds of the embryos. Proflavine 2,8-diaminoacridine is without chemotherapeutic effect on rickettsiae.

There is no evidence that nitroacridin 3582 and *p*-aminobenzoic acid act synergistically on rickettsiae (SMADAL *et al*. 1947b). Nitroacridine is toxic to mice in doses of 200 mgm. per kilo of body weight when given subcutaneously and in doses of 25 mgm. per kilo of body weight after intravenous injection.

The Mode of Action of Acridine Compounds—Observations by McILWAIN (1941 and 1942) and MARTIN and FISHER (1944) show that the bacteriostatic properties of acridines such as acridine and proflavine are inhibited by adenine-containing substances, adenine, adenylic acid, coenzyme and yeast nucleic acid, as well as by certain intermediate products of the action of these substances.

FITZGERALD and LEE (1946) have shown that several of these substances counteract the inhibition of growth of bacteriophage which is displayed by acridine compounds (FITZGERALD and HARRITT 1946). SMADAL *et al* (1947a) found that relatively large amounts of yeast nucleic acid were required to block the rickettsiastatic action of nitroacridin 3582, the ratio being 200 to 1 whereas in the case of bacteriophage the ratio according to FITZGERALD and LEE (1946) was only 25 parts to 1 part of 2-amino-9-(*p*-aminophenyl) acridinium chloride. It seems probable that the mechanism of rickettsiastatic action by nitroacridin is one of interference with the adenine-containing compounds of the organism or host cell in a manner similar to that postulated for bacteriostats (McILWAIN 1941 and 1942 MARTIN and FISHER 1944). ANDREWS and KING (1946) suggest that acridines inhibit the process of rickettsial multiplication by interfering with the acidic phosphoric acid groups, which are salient features of nucleic acid and certain co-enzymes. In any case the mode of action of acridines is different from that of *p*-aminobenzoic acid. It may be noted that the minimal effective dose of nitroacridin 3582 in development, *Lens* eggs injected with *H. mooseri* is slightly less than that of *p*-aminobenzoic acid though both are of the same magnitude. Thus 0.4 mgm. per egg of nitroacridine produces decided inhibition while 0.5 mgm. per egg of *p*-aminobenzoic acid is about the minimal effective dose (HAMILTON *et al*. 1945).

Nitroakridin 3582 has some action on the influenza virus and on viruses of the psittacosis-lymphogranuloma group. It is said to be active against haemolytic streptococci *in vivo* in a dilution of 1 in 250,000 and against staphylococci in 1 in 40,000.

(iii) Antibiotics

GREIFF and PINKERTON (1944), GREIFF *et al* (1944) and MORAGUES *et al* (1944) found that penicillin in large doses had some inhibitory action on the growth of the rickettsiae of murine and epidemic typhus in mice, but against Rocky Mountain spotted fever it was useless (FITZPATRICK 1945). *In vivo*, however penicillin shows little activity, against either louse-borne typhus (YEOMANS *et al* 1944, VAN DEN ENDE *et al* 1946) or against scrub typhus (BLAKE *et al* 1945). Tyrothricin had no action in mice infected with murine or epidemic typhus (VAN DEN ENDE *et al* 1946). The effect of streptomycin on the growth of rickettsiae in eggs is more pronounced (MORGAN *et al* 1947, SMADEL *et al* 1947b and c). In addition to *R. prowazeki*, *R. mooseri* and *R. rickettsi*, *R. akari*, the newly recognized agent of rickettsialpox (HUEBNER *et al* 1946), is affected by doses as small as 1 mgm per egg. The administration of 10 mgm per egg resulted in a distinct lengthening of life of the infected embryos. Curiously enough, *R. orientalis* is scarcely affected by streptomycin. Streptomycin has been shown to have a curative action on *R. burnetii* both in the infected hen's egg and in guinea-pigs (HUEBNER *et al* 1948). Dihydro-streptomycin (DONOVICK and RAKE 1947) has some general rickettsiastatic activity, but it is less than that of streptomycin. The action of streptomycin against rickettsiae is reduced by substances such as semicarbazide (RAKE and DONOVICK 1946) which also reduces the bactericidal action of antibiotics, thus suggesting that antibacterial and antirickettsial action go hand in hand.

Combined treatment of embryos infected with the four susceptible rickettsiae with 10 mgm of streptomycin and 0.5 mgm of *p*-aminobenzoic acid results in a more striking inhibition of growth than is obtained with similar amounts of either drug alone. In a like manner, 10 mgm of streptomycin and 0.4 mgm of nitroakridin display an additive effect in embryos infected with *R. mooseri* and *R. rickettsi*.

LIHLICH *et al* (1947) showed that a *Streptomyces* obtained from the soil of a field near Caracas, Venezuela produced an antibiotic chloromycetin which had a therapeutic effect on *R. prowazeki* in chick embryos. This was confirmed by SMADEL and JACKSON (1947) who found this antibiotic active in chick embryos against *R. prowazeki*, *R. mooseri* and *R. rickettsi* as well as in mice infected with 25 to 100 MLD of *R. orientalis*. In mice 0.1 to 1.5 mgm intraperitoneally or 1.5 to 5 mgm orally were required to cure infection. *R. akari* was also affected in mice and in embryonated eggs. Similar results were obtained in man by PINE *et al* (1948) working with epidemic typhus in Bolivia. Sixteen patients were treated either intravenously or by mouth for three days. Intravenously 10 mgm per kgm was given three times a day for three days while by mouth 15 mgm per kgm was administered without toxic effects. Three to four hours after intravenous injection there was improvement in headache, backache and vision while after oral medication good effects were noted six to eight hours after the first dose. There were no deaths. Similar doses were given to five normal controls without any toxic effects. Recent reports suggest that chloromycetin is of value in scrub typhus in man.

(iv) Dyestuffs

Methylene blue was shown by OTTO and SCHÄFER (1936) to have an action on murine typhus infection in mice, a result confirmed by KIKUTHI and

SCHILLING (1944) in guinea-pigs. PETERSON (1944) used toluidine blue with some success in murine infections in mice.

Later PETERSON and FOX (1944) and McLIMANS and GRANT (1944, 1945 and 1947) found that both toluidine blue and methylene blue were active against *R. orientalis* in mice, while ARISTEUM and RADER (1945) obtained similar results in Rocky Mountain spotted fever. Both dyes are highly effective in mice in the oral maximum tolerated dose of 7.5 mgm. and in cotton rats against intraperitoneal injections of rickettsiae even when therapy is delayed until a systemic infection is well established. Methylene blue is also effective against intracerebral infections in mice, but when given subcutaneously the drug is much less active (PETERSON and FOX 1947). In mice methylene blue appears to be more effective than *p*-aminobenzoic acid against *R. orientalis*.

ANDREWS *et al.* (1946b) tested a number of dyes against rickettsiae injected intranasally into mice and intradermally into rabbits. The results of the two tests were in close agreement. The only dyes which showed any activity were methylene blue, toluidine blue, new methylene blue and 3-diethylamino-7-di-*n*-butylaminophenyl-thionium chloride hydrochloride among thiazines and a selocazine, selenium-methylene blue. Unfortunately the good results obtained in animals have not held good in man. STEELE *et al.* (1946) found that methylene blue, largely owing to its toxicity was without effect in scrub typhus in man. It has been found that the rickettsiastatic action of methylene blue in mice infected with *R. orientalis* is greatly enhanced if the animals are placed in an atmosphere containing 50 per cent. of oxygen (McLIMANS and GRANT 1947). Unlike the acridines and *p*-aminobenzoic acid, toluidine blue and methylene blue are active against rickettsiae *in vitro*. Sodium nitroprusside reduces the acute toxicity of methylene blue (PFEIFFER *et al.* 1943) unfortunately it seems to have very little action on the chronic toxic effects of the drug (PETERSON and FOX 1947).

() Sulphonamide Derivatives

The commoner sulphonamides are without action on rickettsiae. In fact in experiments involving the adaptation of rickettsiae to mouse lung it is usual to give the mice sulphathiazole or sulphadiazine to protect them against secondary bacterial infections.

During the war it was found that some sulphonamides were however active against murine typhus in mice. Of these globocid was the most effective.

Another compound appeared to be equal to methylene blue in its action on

R. mooseri.

The most extensive series of sulphonamides however was that studied by ANDREWS *et al.* (1944) and VAN DEN ENDE *et al.* (1946) in mice inoculated intranasally with murine and epidemic typhus rickettsiae.

The compounds showed activity as follows —

| No | Compound | A* mgm | B* mgm |
|-------|--|-----------|-----------|
| V 147 | <i>p</i> -Sulphonamidobenzamide hydrochloride | 24 | 4 |
| V 186 | <i>p</i> -Sulphonamidobenzamide hydrochloride (free base of V 186) | 24 | 2 |
| V 207 | <i>p</i> -Sulphonamidobenzamide hydrochloride | 16 | 4 |
| V 192 | <i>p</i> -Sulphonamethylamidobenzamide hydrochloride | 16 | 8 |
| V 262 | <i>p</i> -Sulphonamido- <i>m</i> -tolamidoxime base | 16 | 4 |
| V 279 | <i>p</i> -Sulphonamido- <i>m</i> -tolamidoxime hydrochloride | 16 | >8 |
| V 276 | <i>p</i> -Sulphonamido- <i>m</i> -tolamide hydrochloride | 8 | >4 |
| V 231 | <i>p</i> -Sulphonamidobenzamide methyl ether hydrochloride | 16 | 8 |
| V 232 | <i>p</i> -Sulphonamidobenzamide ethyl ether hydrochloride | 8 | 4 |
| V 280 | NN'-Dipropoxybenzamide- <i>p</i> -sulphonamide | 16 | 8 |
| V 281 | NN'-Dimethoxybenzamide- <i>p</i> -sulphonamide | 8 | 8 |
| V 283 | NN'-Diethoxybenzamide- <i>p</i> -sulphonamide | 8 | >8 |
| V 238 | <i>p</i> -Sulphonamidobenzamide ureide | 8 | 2 |

A* = Max tolerated dose for 15 gm mouse
B* = Minimal effective (wholly suppressive) dose given twice daily

All the hydrochlorides in this series were readily soluble in water the free bases were only sparingly soluble. The only compounds having a favourable ratio between toxicity and activity in mice were V 147 and V 186 neither protected guinea-pigs from fever when epidemic typhus rickettsiae were injected intraperitoneally. These drugs had no *in vitro* action on rickettsiae their activity was not abolished by *p*-aminobenzoic acid

Two volunteers who were given 16.79 and 20.38 mgm of V 186 in six days showed no evidence of poisoning. In animals, there was a tendency for the blood pressure to be lowered and the blood urea to be raised. When V 147 and V 186 were tested in patients with epidemic typhus in North Africa and Naples the results were disappointing. The human kidney appears to be extremely susceptible to the action of the drugs. Severe degenerative changes were found in the renal tubular epithelium of fatal treated cases in Naples and a number of unexplained cases of vascular collapse made it inadvisable to increase the dose. The relation between chemotherapeutic action and chemical constitution in this group of compounds is discussed by ANDREWES *et al* (1946a). It is possible that these amidines and amidoximes enter the cell and are built up while nucleic acid synthesis is active, into some essential vital structure of the rickettsiae. It is obvious that only very slight modifications of the *p*-sulphonamidobenzamide molecule are needed to abolish rickettsiastatic action altogether. Many other sulphonamides and sulphones were devoid of action in mice inoculated intranasally. It must however be noted that this method of inoculation fails to demonstrate the protective action of *p*-amino-

(vi) Other Rickettsiastatic Compounds

It has been reported by DURAND and SCHNEIDER (1945) that the 4-aminoquinoline derivative moutoquine (SN 6911) is of value in cases of louse-borne typhus, but these results have not been confirmed. SMADFL *et al* (1947b) failed to determine any demonstrable effect on the growth of rickettsiae in developing hens eggs of several biologically active compounds, tryptophane, riboflavin, folic acid, 7-amino-4-hydroxypteridine-6-carboxylic acid and *p*-amino-benzoyl-L-(+)-glutamic acid. These substances did not influence the rickettsiastatic effect of *para*-aminobenzoic acid.

FERRO-LATZI and FERRO-LATZI (1947) found that intensive vitamin therapy shortened convalescence in typhus but the following methods of treatment were quite useless — Novarsol[†] intravenously, congo red intravenously, mercurochrome, neosarphenamine or calcium intravenously, sulphamidazole, sulphapyridine and penicillin produced somewhat indefinite results. Sodium benzoate and sodium salicylate caused a reduction in mortality and a slight reduction in the duration of the disease but sodium benzoate was associated with an increased liability to complications. Both drugs caused delirium, dizziness, tinnitus and signs of gastric irritation.

More definite results were obtained with aspirin. The first series consisted of 83 Eritreans and 12 Europeans — dosage was either 4 gm. (1 gm. every 6 hours) per day or 8 gm. (1 gm. every 3 hours) per day. Treatment was continued for 2 days after return of the temperature to normal. Only one death occurred among the 94 patients thus treated, whereas among the controls the death rate was 14.8 per cent. — the duration of the disease was 11.1 days in treated as against 14.8 in untreated cases, while 23.8 per cent. of the treated had complications as against 37 per cent. of the controls. In a second series treated in 1947 74 patients were given aspirin. 11 were left as controls. The mortality among the controls was 10.7 per cent., among the treated 3.4 per cent.

Forbes, 4,4'-bis-antipyrine, was shown by PETERSON (1944) to have some action on murine typhus.

VAN DEN ENDE *et al* (1946) tested a very considerable number of alkaloids, arsenicals, aromatic amidoximes with sulphur, aromatic amides with sulphur, aromatic guanidines, biguanidines, amides and amidoximes with sulphur, groups, pyrimidines and miscellaneous compounds with completely negative results.

Riboflavin deficiency has been found to render the peritoneal cells of the rat susceptible to typhus and riboflavin therapy is then effective against the infection. Large amounts of riboflavin are however therapeutically ineffective in typhus-infected normally fed mice. In view of the importance of high vitamin therapy in typhus it is of interest to note that in 1904 HILARY found yeast of great value in severe typhus infections. If the tissues of different species differ in their content of essential metabolites or enzymes this may possibly explain the varying response of different species to the same chemotherapeutic agent.

SUMMARY OF RECENT ABSTRACTS

VL PLAGUE

Epidemiology Transmission

DAVIS (p. 6) describes the outbreak of plague in Ngamiland during 1944-45 which was the biggest ever recorded in South Africa. It took its origin in gerbils (*Talor*) which are subject to epizootics of plague and from which the

The information from which this series of summaries has been compiled is given in the abstracts which have appeared in the *Tropical Diseases Bulletin* 1947, v 44. References to the abstracts are given under the names of the authors quoted and the pages on which the abstracts are printed.

infection is commonly spread to the multi-mammate mice (*Mastomys*) which make use of gerbil burrows and pick up the fleas (*Xenopsylla eridos*). These mice also approach human habitations and transfer the infection to domestic rodents, whose fleas (*X. brasiliensis*) are effective vectors to man.

TOMIC (p 996) has failed to find infection in a small number of rodents examined in the Suez Canal Zone, there is no definite evidence that sylvatic plague exists there.

RAO (p 816) found that field rats near a village in India where plague was endemic were very susceptible to the disease, and he therefore argues that they have not been in frequent contact with the disease, and cannot be the cause of the endemicity in that area. It therefore seems a waste to fumigate rat holes in the fields, and attention should be concentrated on the more resistant rats of the village itself.

MACCHIAVELLO (p 519) reports a focus of sylvatic plague on the borders of Peru and Ecuador.

MIYARA and his colleagues (p 815) describe the very great epizootic of plague which exists in the wild rodents of Argentina and several outbreaks which have occurred in man, largely as a result of handling dead rodents. Pneumonic plague has occurred, which is difficult to diagnose and which spreads from man to man. Prevention entails education in the danger of handling wild rodents, and isolation of the patients in hospital. Sera and vaccines are not regarded as useful, and anti-rat measures, essential for towns, are not applicable to the conditions of sylvatic plague.

HUMPHREYS and CAMPBELL (p 758), as a result of surveys made in Canada, point out that plague is well established in ground-squirrels in parts of Alberta and Saskatchewan. So long as it is confined to these squirrels there is not much danger to man, but if rats invade the area and become infected, the problem will be serious. Rats are well established in the towns.

WAYSON (p 899) discusses the results achieved in field surveys in the United States during 10 years, when enormous numbers of rodents and fleas were examined. One infective flea can infect a series of animals. There is no evidence that rodent carriers of subacute or chronic plague are a factor in perpetuating the disease from one season to another but it seems likely that some form of recrudescence in the carrier of quiescent disease is necessary for carry-over by infection of fleas. PRINCE and WAYSON (p 816) have shown that a flea can remain alive and infected with plague in a virulent form for a period of 4 months in the nest of a hibernating squirrel but most of the fleas which were infected and remained alive did not retain the infection for the entire 4 months. The same authors (p 1064) show that a squirrel in whose skin plague is introduced while the animal is in hibernation in October may awaken 4 months later and subsequently develop acute manifestations of the local lesion, and lethal bacteraemia. A flea infected in October and placed on a healthy hibernating squirrel can retain the infection and transmit it during the following March.

Although at one time it was assumed that fasting fleas could not live longer than one month, and therefore that a voyage lasting 80 days ruled out the possibility of introduction of plague by fleas alone, MACCHIAVELLO (p 997) has shown that fleas taken alive in jute bags imported into Peru from India were capable of inducing plague by bite, although there was no possibility that the fleas could have received their infection during the voyage.

PERRY (p 76) and LAURIE (p 76) have written on the reproduction of the brown rat and the house mouse respectively. The papers are technical and detailed but have a bearing on studies of the rodent hosts of plague and indicate some of the mistakes that can be made if the subject is not studied with some care.

Etiology

GIRARD (p. 520) indicates the importance of distinguishing between *P. pestis* and the pneumococcus in the diagnosis of plague pneumonia. Cultures should therefore be incubated at 20-28°C., not at 35°-37°C. and for inoculation or scarification tests, guineapigs rather than mice should be used since the latter are very susceptible to the pneumococcus. This organism may exert an antibiotoxic action on *P. pestis* and may prolong the incubation period to 10 days in primary plague pneumonia. In Madagascar the authorities have fixed a limit of 10 days for quarantine of contacts.

LAZARUS and GUNNISON (p. 1064) show that differentiation between *P. pestis* and *P. pseudotuberculosis* by phage action is not reliable. They also found that *P. pestis* phage acted on some strains of *Salmonella* and *Shigella*.

GIRARD and SANDOR (p. 800) have studied the toxin of *P. pestis* a protein which may be injected as whole bacilli, or as a solution since it diffuses into liquid culture media. It is not an exotoxin. RABOIX *et al.* (p. 800) show that plague toxin differs from true exotoxins in that certain antibiotic substances do not act on it.

Clinical Findings and Treatment

Although meningitis is not regarded as one of the common lesions in plague LAXENBOROUGH and TUNNELL (p. 418) report 8 cases, all fatal, in a total of 203 cases. *P. pestis* was found in the spinal fluid in 5. In one the meningitis appeared to be primary but in the remainder it was a sequel of bubonic disease.

SORHEY and WAGLE (p. 418) discuss the treatment of septicaemic plague noting that septicaemia is the most important single factor determining death or recovery. They found that sulphadiazine (4 gm. followed by 2 gm. every 4 hours for not more than 10 days) gave the best results reducing case mortality from 91 per cent. in controls treated with intravenous iodine to 31.9 per cent. Sulphathiazole was not so useful. The authors treated 1,604 patients in all.

SIMMONS and CHATRE (p. 77) found sulphadiazine more effective than sulphathiazole in the treatment of bubonic plague in India.

HUANG and CHU (p. 419) note that plague bacteraemia is readily controlled by sulphonamides especially sulphadiazine but that viable bacteria remain unaffected within tubercles and may cause relapse.

MAGROU (p. 417) reports an outbreak of plague at Ferryville Tunisia, in which there were 37 cases and 10 deaths. Only 2 deaths occurred in the 28 who were treated with sulphadiazine. The Girard live vaccine was given to 60,000 people.

ROUX and MERCIER (p. 207) report that three of five patients with pneumonic plague were cured by administration of 65-75 gm. sulphathiazole. This is a striking result.

ALBERTO VIDELA (p. 659) has treated several cases of plague with sulphonamides and streptomycin in one with signs of meningitis, intrathecal administration of streptomycin was followed by striking improvement. HERBERT (p. 713) shows that streptomycin kills *P. pestis* in culture and is an effective treatment (more so than sulphathiazole) in mice and guineapigs infected with plague.

Vaccination Control

BAKER *et al.* (p. 712) have investigated the antigenic structure of *P. pestis*. Various fractions were isolated one of which, a carbohydrate protein fraction, is probably the normal antigen of the intact cell, and is an envelope antigen. For vaccines all the antigens should be included.

MEYER (p. 816) sums up the measures taken to control plague. Recent work indicates that success in vaccination depends rather upon the actual mass of

bacterial protein injected than on the method of preparing the dead antigens, and that organisms grown on agar and killed by formalin are effective if enough are injected and if frequent "booster" doses are given. Urban plague, except in a few areas, is no longer a major problem, but sylvatic plague may be so. It is not known why human cases are so rare, although rodent plague is so very common, in the 14 States of the U.S.A. which are affected.

WAYSON *et al* (p 419) give the results of experiments with guineapigs which indicate that plague vaccines prepared from organisms grown at 39°C and killed by phenol or formalin, are effective in preventing death of the animals. In a city of 110,000 inhabitants, in India, SIMEONS and CHHATRE (p 77), inoculated 90,000 with a single dose of killed plague vaccine (Haffline), in the face of an epidemic. The results were disappointing, and the authors conclude that it would be dangerous to rely on vaccination of this type, given as a single dose, and that the use of cyanogas, rat-bait and anti-flea measures is much more valuable.

The Indian Research Fund Association report on plague (p 997) shows that plague vaccine (either casein hydrolysate or agar vaccine) deteriorates if kept at 37°C, but not nearly so much at 0°C.

GRASSET (p 419) shows that a live avirulent plague vaccine has been largely used in South Africa, and that in 24,000 persons inoculated with it, there occurred only 15 cases of plague. The vaccine can be dried at low temperatures and kept for 2 years with little loss of antigenic power. Sylvatic plague is a very great problem in South Africa.

MACCHIAVELLO (p 78) and his colleagues (p 713) describe the use of DDT and of the rat poison sodium fluoracetate (R^{1080}) in stopping an epidemic of plague in a city in Peru where most of the rats were *R. rattus alexandrinus* and most of the fleas were *X. cheopis*. DDT as a 10 per cent powder was applied to the floors of all houses and left unswept for a week and elsewhere in likely rat harbours. Sodium fluoracetate was incorporated in bait and placed with care out of reach of children. These measures were most successful. The author notes that 10 per cent DDT is toxic for rats (which lick their fur), and that sodium fluoracetate is toxic for fleas which suck the blood of poisoned rats.

ELISHEWITZ (p 1064) advises that places frequented by rats should be dusted with DDT, to kill fleas and their larvae, and that alpha-naphthyl thiourea (ANTU) or sodium fluoracetate should be used for the rats, but with care and by skilled operators only. DDT and the modern repellents can be used in clothing, for the protection of field workers. GOUCK (p 78) has found 10 per cent DDT in pyrophenylite successful against fleas on rats, when it is dusted in their holes and burrows.

Reporting an outbreak of plague in Algeria, which was not pneumonic and in which no rats could be found, either alive or dead, GRENOILLEAU (p 658) suggests that the disease was probably transmitted from man to man by *Pulex irritans*. Control action in such an outbreak comprises prompt detection and isolation of cases, disinsection of patients and contacts, and daily medical supervision of contacts, as well as the other usual methods.

The flea *Synosternus pallidus* may be a vector of plague in Dakar, and KARTMAN (p 420) has shown that DDT, either as a solution or as a dusting powder is effective against this flea, when applied in huts.

Charles Wilcocks

RABIES

OTTEN L. Investigations into Rabies. II. *Antonie van Leeuwenhoek J Microbiol. & Serol.* 1947 v 13, Nos. 2/4 101-27 1 fig (21 refs.)

In this posthumous contribution of the late Prof. OTTEN detailed reference is made to the statistical and experimental work on rabies carried out by his deceased wife Maria J. OTTEN-VAN STOCKUM at the Pasteur Institute, Bandoeng, Netherlands East Indies.

The following paragraphs summarize the more important conclusions reached during a prolonged period of research —

The rate of mortality from rabies during or after treatment provides no reliable index of any particular treatment's efficacy: the sole criterion in this respect being a reduction in the occurrence of "failures" defined as cases in which symptoms appear more than 30 days after treatment has begun.

Monkey brain furnishes a more active antigen than rabbit or sheep brain and in anti-rabies immunization the superiority of monkey brain fixed virus (both living and formalized) over other vaccines is evidenced by the subjoined comparative results —

| Method of treatment and when practised | No. of persons treated | No. of deaths | Percent mortality | No. of failures | Percent failures |
|---|------------------------|---------------|-------------------|-----------------|------------------|
| Pasteur method (1893-1905) | 1421 | 9 | 0.56 | 7 | 71.7 |
| Hogyes method (1906-1916) | 1610 | 4 | 0.25 | 1 | 3.0 |
| Monkey brain FV (living and dead) (1916-1940) | 2919 | 2 | 0.07 | 0 | 0.0 |

At Bandoeng during a 25 years period there was no "failure" among persons treated in the first week after the bite whether with living (1916-32) or with killed, formalized (1933-40) monkey brain FV. The vaccine most recently employed derives from a 10 per cent suspension of monkey brain in a 1.5 per 1000 concentration of formalin heated for 5 days at 37°C. Prior to its administration it is diluted to 2 per cent and the total quantity injected, over a 14 or 21-day period, is 1120-1,520 mgm., as against 470 mgm. of the living virus vaccine previously in use.

Two weeks' treatment was found to be as effective as a 3 weeks' course when judged by the failure rate and the rabiecidal antibody content of inoculated persons sera.

The fact that the average period of incubation in cases of rabies treated with formalized vaccine shows a definite shortening when compared with those treated with live vaccine not only disproves the statement of VICTOR (Cited *Bull. L. Abt. Orig.* 1946 4, 647-775) and of PROCA and BOSTA (*this Bulletin* 1940 v 37 618) that the shortening is to be ascribed to the action of live FV but also encourages the hope that by the use of formalized vaccine the immunization process will attain its maximum more rapidly — within the first 30 days following the commencement of treatment — within the defined failure limit — and first of all after reduction in mortality.

Formalized vaccine when prepared as a 2 per cent suspension and stored at room temperature rapidly lost potency stored as a 10 per cent suspension at 5°C, however it showed no appreciable decrease in activity. Decontamination

of treatment is thus possible if the original 10 per cent suspension, preserved regionally under adequate storage conditions, is diluted to 2 per cent immediately before its administration

The testing of a 10 per cent suspension before and after centrifuging showed that both in virulence and antigenic activity the supernatant fluid was much inferior to the ordinary suspension and to the deposit

An experiment devised to ascertain whether, over a 14-day period, the immunization of the rabbit and the guinea-pig (in a total dosage of 20 mgm and 10 mgm respectively) could better be effected by consecutive daily injections of slowly increasing strength or by three adequately interspaced injections of increasing strength failed to show any difference in favour of the daily injection

IRR, G La prophylaxie de la rage Police sanitaire et vaccination preventive [Prophylaxis against Rabies. Sanitary Control and Preventive Inoculation] *Cahiers Méd Union Française* Algiers 1947, Oct, v 2, No 13, 615-31 [12 refs] G Stuart

The author deplores the comparative failure in France and in French North Africa of the sanitary regulations prescribed for the prevention and control of rabies. He attributes this failure, not to the inadequacy of the regulations themselves but to the fact that the requisite powers of enforcement are vested in local rather than in central authority. He compares the state of affairs in France unfavourably with that in Great Britain, where similar legislative measures have been enforced by central authority (the Ministry of Agriculture) since 1899.

In discussing the actual measures to be adopted the author urges large scale vaccination of dogs—free of charge to the owners—and goes so far as to state that vaccinated dogs are no longer susceptible to rabies.

He proposes the adoption of a specific programme for Algeria and includes therein a suggestion whereby the practice of canine prophylaxis may be stimulated *viz*, a relaxation in the case of vaccinated dogs of sanctions otherwise immediately imposed by the law. Thus a vaccinated dog having been in contact with an animal suspected of rabies would be subject to surveillance at home instead of to summary destruction. (Such leniency contrasts sharply with the measure in force which prohibits dogs from appearing on public thoroughfares unless muzzled and on the leash.) He further recommends that dog shows should be open only to those animals vaccinated against rabies.

Other measures in common practice elsewhere are also dealt with in the paper: the impounding and destruction of all stray dogs, the compulsory wearing of collars with ownership clearly indicated.

The author feels confident that the adoption of such a programme, coupled with the transfer of overall powers of enforcement from the communes to the prefectures would materially improve the far from satisfactory rabies situation existing in Algeria today.

REMINGER P & BAILLY, J La rabia del lobo Criterio de la vacunación pasteuriana [Wolf Rabies and the Assessment of Pasteurian Vaccination] *Med Colonial* Madrid 1948 Mar 1 v 11 No 3, 115-18 G Stuart

MALARIA

PALLIACCIOTTA R. Note sulla morbidità malarica nella zona Dire-Dana-Erer dell'Etiopia. [A Note on Malaria Morbidity in the Dire-Dana-Erer Area of Ethiopia.] *Atti Med Italica*, 1948 Jan. v 3 Supp. No. 1 25-8.

The English summary appended to the paper is as follows:—

"The author has studied the malaria morbidity in the region of Dire-Dana-Erer in Ethiopia, observing in many subjects, many of them without temperature presence of many malaria parasites in the blood.

"He calls attention to the high endemicity of the malarial infection in that region."

DALAL, P. A. Bombay and its Malaria. *Indian J Med Sci* 1947 Dec. v 1 No. 8 75-91 [11 refs.]

In this lecture the author refers to the outstanding epideemics of malaria that have afflicted Bombay City in the past to the numerous surveys and special investigations that have shown how the disease might be controlled, or even eradicated, at no prohibitive cost and the failure of the authorities to take effective steps to that end. No new facts are adduced but information regarding the local habits of the only vector *A. stephensi* is well summarized.

Norman White

ESTELA GASTELO Mannel A. Encuesta malarica de reconocimiento del Valle de Cañete. [Malaria Survey of the Cañete Valley] Publicaciones de la Dirección General de Salud Pública, Departamento de Malaria. 88 pp. 2 maps, 4 charts & 8 plans. [14 refs.] 1947 Feb. Lima, Peru.

The Cañete Valley is the southern part of the Province of the same name which forms the south-eastern part of the Department of Lima. The Valley covers an area of 21,800 hectares its mean altitude is 98 metres above sea level. Its estimated population is 31,710. The Valley watered by the River Cañete has a maximum width of 20 km. elsewhere its width varies from 13 to 17 km. It is very fertile. The geography hydrography geology and agriculture of the Valley are outlined and information is given about the social and economic conditions of the population. Pneumonias, pulmonary tuberculosis and enteritis are responsible for most deaths. Deaths attributed to malaria have declined markedly during the last decade. The malaria death rate in 1944 was 1.49 per thousand (49.32 per thousand all causes). 3,818 cases of malaria were reported with 18 deaths. Malaria is most prevalent during the first seven months of the year.

In November and December 1945 2,210 children below the age of 11 were examined. 295 (13.3 per cent) had enlargement of the spleen. In 101 of these the spleen was palpable only on deep inspiration in 117 others it did not extend beyond the costal margin in 20 the spleen reached the umbilicus.

The blood of 2,167 of these children was examined parasites were found in 107 (4.9 per cent.). The percentage incidence of parasit species was *P. m.* 54%, *P. falc. par.* 34.4 and *P. malariae* 11.4.

Only two species of *Anopheles* were found *A. pseudopictipennis* and *A. punctimans*. The former is the chief vector of malaria it is widespread, markedly anthropophilic and frequents human habitations. *A. pseudopictipennis* was only rarely found breeding and only occasionally captured in dwelling houses. It too shows a predilection for human blood but its role as a malaria vector has yet to be defined.

Norman White

KETTLE, D S & SELICK, G The Duration of the Egg Stage in the Races of *Anopheles maculipennis* Meigen (Diptera, Culicidae) *J Animal Ecology* 1947, May, v 16, No 1, 38-43, 2 figs [12 refs]

Wild-caught females of various races of *Anopheles maculipennis* were allowed to oviposit in small cages and the times of hatching of the eggs were observed. The data presented in this paper were collected in Italy in the spring of 1945 and analysis shows that at 10°C eggs of *A m maculipennis* develop more rapidly than do the eggs of either *A m labranchiae* or *A m melanoon*, but the difference becomes less at higher temperatures until at about 20°C it is negligible. The following examples are extracted from a table of mean incubation periods: eggs of *A m maculipennis* 10 days at 10.6°C and 4.2 days at 16.5°C, eggs of *A m labranchiae*, 12.6 days at 10.6°C, and 4.2 days at 17.3°C, eggs of *A m melanoon*, 12 days at 10.8°C and 4.5 days at 17.0°C. The authors suggest that the quicker development of the eggs of *A m maculipennis* at the lower temperatures is possibly an adaptation to the more rigorous climate to which this race is exposed in its natural habitat as compared with that of the other races.

KARTMAN L NEWCOMB E H CAMPAU E J & MORRISON F D Mosquitoes collected in Dakar, French West Africa, incidental to Army Malaria Surveys *Mosquito News* 1947 Sept v 7 No 3 110-15

WHITE, R Senior An Analysis of a Series of Night Catches of *Anopheles* *J Malaria Inst of India* 1946 Dec, v 6, No 4, 417-23

These catches of anophelines were made in 5 localities outside the control area of the Korea Coalfield in the Hazaribagh Ranges in Central India. The catches were made for the first twenty minutes of each hour from 11.0 p.m. till daylight six times a month for 21 months.

Eleven species were obtained, but only three were collected in sufficient numbers to merit tabulation: *A culicifacies*, *A fluviatilis* and *A subpictus*. *A culicifacies* shows maxima in May, August and October. Hourly incidence decreased steadily from 23.00 to 5.00 hours and was followed by the usual increased entrance before dawn.

Captures of *A fluviatilis* were almost confined to October and November, when they represented 92 per cent of the year's total. Prevalence of this species was highest before midnight and decreased till the pre dawn entrance.

Dissections have hitherto incriminated only *A fluviatilis* as a vector of malaria in this part of India. Malaria transmission however is active between July and September when this species is all but absent. *A culicifacies* is probably responsible for this in spite of the failure of dissections to confirm it.

REID J A Type Specimens of Culicidae described by Laveran (Diptera Culicidae) *Proc Roy Entom Soc of London* Ser B Taxonomy 1947, Aug 15 v 16 Pts 7/8, 86-91 [12 refs]

The author has been able to examine the original type specimens of six species of mosquitoes (two from Oceania and four from Indo-China) described by Laveran in 1901-1902. Perhaps the most interesting discovery relates to the identity of *Anopheles farauti* a member of the *p. inclutus* group occurring in the New Hebrides. Examination of Laveran's original material shows that *A. farauti* is defined by Knight and other recent American authors is identical with Laveran's original material. For this information all students of this difficult group will be grateful.

MACKERRAS M. J. & ROBERTS F. H. S. Experimental Malarial Infections in Australasian Anophelines. *Ann. Trop. Med. & Parasit.* 1947 Dec., v 41 No. 3/4 329-58 9 graphs. [74 refs.]

This investigation was undertaken in 1943 at Cairns, North Queensland, for the purely practical purpose of discovering the most useful mosquito to employ in the laboratory study of malaria transmission. The breeding and infecting of anophelines was done on a very large scale. 233 000 engorged mosquitoes were used, 38,000 dissections were performed and 20 000 infected bites were inflicted. Seven species were from Queensland, *Anopheles punctulatus farauti*, *A. annulipes*, *A. annulatus annulatus*, *A. annulatus hilli*, *A. meranthensis*, *A. bancrofti bancrofti* and *A. stigmaticus* two were from New Guinea, *A. punctulatus punctulatus* and *A. longirostris*. A colony of *A. p. p. punctulatus* was eventually established, as supplies of the other species became insufficient. This colony flourished successfully until the work ceased in 1948.

The techniques of collecting, rearing, feeding and infecting the mosquitoes are described. The characteristics which influence an anopheline mosquito in malaria transmission were studied. One of these abundance was satisfied in the laboratory by *A. p. punctulatus* as it colonized so readily that adequate numbers were always available. All species would feed on man, but *A. p. punctulatus* was more avid for human blood than the others. *A. stigmaticus* and *A. longirostris* would feed only with reluctance. The authors regard longevity as a most important factor in laboratory work, perhaps even more so than willingness to feed. *A. p. punctulatus* was the longest lived species. It needed a humid atmosphere and a temperature about 70 to 75 F (21 to 24°C.) and not less than 6 cubic inches of space per mosquito. It needed also freedom from disturbance for it was found that overcrowding and frequent handling of the cages shortened life by keeping the insects in a state of abnormal activity. The two rare species *A. longirostris* and *A. stigmaticus* showed evidence of insusceptibility to infection. All the common species were highly susceptible though there were, of course individual variations in all species.

Finally a most careful study of *A. p. punctulatus* showed that this species was the most useful in transmission experiments, in all respects. There was however no marked difference between *A. p. farauti* and *A. annulipes* in the laboratory studies, though the former is an important natural vector while the latter is not.

STACE, H. H. & GILLETTE H. P. S. Observations on Mosquitoes and Malaria Control in the Caribbean Area. Part III—Trinidad. *Mosquito News*. 1947 Dec. v 7 No. 4 157-9 2 figs.

Fifteen species of *Anopheles* are known to occur in Trinidad and T. bago of which the following five species are common. *A. aquasalis* the most important malaria vector. *A. bellator* an important vector in the heavy rainfall zones. *A. acromialipalpus* and *A. altitarsis* both suspected as minor carriers and *A. costalis* a zoophilic species.

Catches in Shannon dawn traps have proved that *A. aquasalis* has migrated inland over rough country as far as five miles from its salt marsh breeding places.

In the cacao estates tall shade trees called umbrocelles (*Erythrina* spp.) are interplanted. These immortelles support a considerable flora of sun epiphytes of which the bromeliads are most numerous. The common bromeliad (*Guzmania sp.*) breeds enormous numbers of *A. bellator*.

The difference between the leaves of bromeliads, cacao and immortelles has made it possible to use several chemical weays as bromeliads. But results

have been obtained with 0.5 per cent copper sulphate and plans have been made to replace the immortelles with other trees as wind breaks, so that with the eradication of the breeding places of *A. bellator* endemic bromeliad malaria should disappear from Trinidad

KIVITS, M. Infection malarienne à *Pl. vivax* [Relapsing *P. vivax* Malaria]
Ann Soc Belge de Méd Trop 1947, Sept 30, v 27, No 3, 333-5

The author returned on leave from the Belgian Congo in September 1946, after 8 years' continuous residence during that time he took daily prophylactic quinine regularly (0.3 to 0.4 gm). He had occasional light attacks of malaria. On his arrival on leave, on September 15, he had completed a suppressive course of quinine (1 gm daily for 15 days). At the end of September he had a typical tertian ague, which was treated with quinine (0.25 gm three times the first day, then 1.5 gm daily for 5 days and 1 gm for 8 days).

Towards the end of October, he had another attack, again treated with quinine (1.5 gm daily for 4 days), followed by mepacrine (0.1 gm three times daily for 5 days). A third attack occurred in December (similarly treated), and a fourth in January the latter was mild and responded well to quinine. The author had a mild febrile attack in February, and in March yet another appeared. He then procured some Paludrine and took the recommended dosage of 3 tablets of 0.1 gm daily for 10 days. He took 15 days' holiday in the country and felt better than he had during the first six months of his leave.

In the middle of May, 6 weeks after the course of Paludrine, he developed another attack having no Paludrine at hand, he used quinine again. On this occasion blood films showed many amoeboid forms of *P. vivax* showing the "tenacity of the infection and the failure of the 'suppressive course' of Paludrine."

After this attack was treated with quinine [dosage not stated] together with Stovarsol the author took Paludrine again in a dose of 1 tablet twice weekly or 6 months. He notes that his wife had attacks comparable to his own, with elapses throughout their leave. She however, took the first "suppressive course of Paludrine in the form of 30 tablets in 15 days instead of in 10. The lapse occurred five days after that of her husband.

The author points to the importance of recognizing relapsing *P. vivax* infection in persons returned from the Tropics and of the need for a prolonged course of Paludrine

Doctors have to be on the alert to recognize and to treat malaria because so many persons returning from Netherlands India and from confinement during Japanese occupation are arriving in Holland. This brochure is simply and clearly set out for the use of those who are not familiar with the subject in the

home country. Quinine treatment is stressed particularly for quinine is regarded as an essentially national medicine. The short cure is advocated and, as example, this may be given for benign tertian malaria — 1 dose of quinine hydrochloride or quinine sulphate of one gramme daily is administered until the temperature is normal and then one gramme daily is given in continuation for 5 days. This usually means a total treatment of 6 to 8 days. If a relapse occurs, precisely the same treatment is carried out and so with each relapse. No advantage is claimed for quinine hydrochloride or bisulphate which are more soluble, over the less soluble quinine sulphate. Diagrams are given to explain the method of intramuscular administration and a series of six coloured plates at the end show for *P. vivax*, *malariae*, *falciparum* and *ovale* the stages from young rings through amoeboid forms with Schüffner stippling, schizont and merozoites, to male and female gametocytes. Three of the plates are those of thick drop appearances and a final table sets out differentially the appearance of each species of malaria parasite in stained films.

STRAMAN J. H. Quinine by Continuous Intravenous Drip in the Treatment of Acute Falciparum Malaria. *Trans. Roy. Soc. Trop. Med. & Hyg.* 1948, Mar. v. 41 No. 3 369-78. [20 refs.]

During the Japanese occupation of Malaya, the author was able to observe the records of nearly 2,000 cases of acute *Plasmodium falciparum* malaria in malnourished British, Australian and Dutch prisoners near Singapore. Treatment was based on quinine followed, so long as stocks lasted, by mepacrine and plasmoquine. Severe infections were treated with quinine by intramuscular or intravenous injection—the latter almost entirely by standard methods. This paper records clinical and parasitological details of 15 patients treated by a continuous intravenous drip technique.

Approximately 1,000 cases were seen between February 1942 and September 1944—the majority were in 1942, one of the worst periods of malnutrition. No record of the number of intravenous injections is available but it is small. Solution for injection contained 1 grain of the hydrochloride in 2 cc. of saline the rate of injection being 2 cc. a minute and the usual single dose 0.5 to 0.68 gramme. Four fatalities which were apparently due to this method are recorded, namely—

1. Heavy infection with *P. falciparum*. Intravenous injection 0.5 gm. immediate epileptiform convulsions and death.
2. Very heavy infection with *P. falciparum*. Intramuscular quinine 0.1 gm., followed in 1 hour by 0.2 gm. intravenously. 20 minutes later collapse and death.
3. Moderate *P. falciparum* infection. Died during an intravenous injection (dose not given).
4. Heavy *P. falciparum* infection. 1.0 gm. quinine intravenously in 5 c.c. water. Immediate epileptiform convulsions and death. A large and concentrated dose.

In addition, there was a case of *P. falciparum* malaria in which during mepacrine treatment a convulsion occurred and death followed immediately after 0.5 gm. quinine intravenously.

Approximately 1,000 other cases were admitted between October 1944 and September 1945. Usually all those with over 100 parasites per thick field (Faulk's method) were given primary intramuscular injection of 0.5 gm. quinine. When the thick film showed considerably more than this number a parasite count was made. When this was over 100,000 parasites per cmm. (estimated by total red cell counts and the number of trophozoites per 100 red

cells) intravenous drip quinine was given regardless of the clinical condition, and also where cerebral or other pernicious signs were present

A Soluvac or Vacolite gravity flask, with drip regulator and tied-in cannula was used. The vehicle was sterile normal saline, sometimes with an intravenous preparation of thiamin added. In each case, 2 gm of quinine bihydrochloride were given in 24 hours, 0.5 to 0.66 gm per litre. The rate of flow was 30 to 40 drops per minute. The long saphenous vein at the ankle was chosen for injection, to allow use of the arms. The leg was placed on a back splint with a footpiece. The drip was continued for 12 to 96 hours, according to the severity of the case. 15 cases so treated are described in detail. The advantages of this method were (a) ease of combination with other treatment, thus 2 patients received 600 cc of blood for gross anaemia, (b) certainty of complete absorption, (c) certainty of a constant safe concentration of quinine without degeneration products producing inefficiency, (d) absence of unpleasant 'ter-effects.

The disadvantage was some mild phlebitis of the vein when the cannula was *in situ* for 2 or 3 days, with risk of severe septic phlebitis. Of the 15 patients so treated two died, one on the 3rd day from tonic spasm, 3 hours after starting the drip, the second from pyaemia due to sepsis at the site of the drip on the 28th day. This patient on admission had 1,240,000 parasites per cmm of blood, while four had over 500,000, and all were in very poor condition.

FIELD and NIVEN [this *Bulletin*, 1937, v 34, 615] in an analysis of 750 cases of *P. falciparum* malaria on the 1st day of treatment concluded that 750,000 parasites per cmm in the peripheral blood was about the extreme limit of tolerance in Asian adults for the Malayan strain, and FIELD in a series of 2,000 cases records no recoveries where the count exceeded this figure (unpublished). A combination of starvation with a heavy malarial infection is very dangerous. FERNANDO and SANDARASAGARA in Colombo [*ibid*, 1936, v 33, 687] found that intravenous quinine was contraindicated when the systolic blood pressure was below 90. The author considers that the drip method of using intravenous quinine in a dilute form sufficient to secure administration of 2 gm in 24 hours is a safe and efficient one. Recovery is recorded of 3 cases with a peripheral intensity of infection higher than has been hitherto recorded in Malaya (871,000, 925,000, and 662,000 parasites per cmm respectively). C F Shelton

JAILER J W ROSENFELD M & SHANNON, J A. The Influence of Orally Administered Alkali and Acid on the Renal Excretion of Quinacrine, Chloroquine and Santoquine. *J Clin Investigation* 1947, Nov, v 26, No 6 1168-72 [11 refs]

HAAG *et al* (*J Pharm & Exper Therap*, 1943 v 79, 136) found that the urinary excretion of quinine given orally in a single dose was related to the pH of the urine the output being increased if it were made acid. Other authors [this *Bulletin* 1945 v 42, 780] have drawn attention to the correlation between urinary output of quinacrine (atebrin mepacrine) and ammonia. The effect of alkali and acid given by mouth on the urinary excretion of quinacrine, chloroquine and santoquine (the two latter being antimalarials of the 4-aminoquinoline series) has now been investigated. The patients were in the older age groups and the drugs were given orally in high initial dose on the first day, followed by a smaller maintenance dose on several succeeding days till the plasma levels were fairly constant. Sodium bicarbonate was given during the day in seven doses of 2.5 gm and a similar dose during the night (total 20 gm), which raised the pH of urine to 7.5 or 8. Ammonium chloride, as the acid, was given

home country. Quinine treatment is stressed particularly for quinine is regarded as an essentially national medicine. The short cure is advocated and, as example, this may be given for benign tertian malaria.—A dose of quinine hydrochloride or quinine sulphate of one gramme daily is administered until the temperature is normal and then one gramme daily is given in continuation for 5 days. This usually means a total treatment of 6 to 8 days. If a relapse occurs precisely the same treatment is carried out and so with each relapse. In addition, there was a case of *P. falciparum* malaria in which during mepracrine treatment a convulsion occurred and death followed immediately after 0.5 gm. quinine intravenously.

Approximately 1,000 other cases were admitted between October 1944 and September 1945. Usually all these with over 100 parasites per thick field (Field's method) were given a preliminary intramuscular injection of 0.5 gm. quinine. When the thick film showed considerably more than this number a parasite count was made. Where this was over 300,000 parasites per cmm. (estimated by total red cell counts and the number of trophozoites per 100 red

They then report the results of a number of experiments with paludrine. A patient was infected with the Rumanian strain of *P falciparum*. The primary attack and the first two relapses [= recrudescences] were lightly treated with paludrine or quinine. The third relapse was allowed to proceed unchecked and it produced a good crop of gametocytes, which readily infected a control batch of mosquitoes—*Anopheles maculipennis* var *atroparvus* (87.5 per cent positive). Paludrine was then given in two divided doses of 0.4 gm each and batches of mosquitoes were fed daily on the patient for 8 days after the administration of the drug and again on the 12th day. Samples of mosquitoes were dissected at appropriate intervals and the results indicated that up to and including the seventh day after paludrine, the mosquitoes failed to become infective—thus confirming Farley's work at Cairns [this *Bulletin*, 1946, v 43, 527].

Exflagellation of the male crescent occurred normally, and ookinetes were plentiful in all the experiments, and the first indication that paludrine was having an adverse effect, was the small number of oocysts appearing on the wall of the mid gut. The authors suggest that it is the females upon which the drug acts, without however giving any very satisfactory proof.

[The planning of this experiment is perhaps not quite satisfactory, as the control only refers to the conditions prevailing at the very beginning of the "crescent wave". It is important to view all work relating to the sexual phase of *P falciparum* against the highly characteristic background of this phenomenon—as described for instance by the reviewer (this *Bulletin*, 1931, v 28, 995).]

FARRELL, E. The *Anopheles gambiae* Problem in Brazil and West Africa, 1941-44. *Bull U S Army Med Dept* 1948, Feb, v 8, No 2, 110-24, 11 figs [Refs in footnotes].

Following the "unparalleled disaster" for the inhabitants of certain of the north-eastern states of Brazil because of *gambiae*-transmitted malaria, the joint efforts of the Rockefeller Foundation and the Brazilian Government had by 1940 eradicated *A gambiae* from Brazil, "one of the finest public health achievements of the age". During the recent war, Brazil lay astride the heavily used airborne traffic routes from the U S A and the Caribbean to the Mediterranean and Middle East Theatres of War via Senegal or Liberia or the Gold Coast.

The introduction of *A gambiae* by air traffic to Brazil and the Caribbean was therefore an ever-present possibility. Indeed, with increase in this traffic, the Brazilian Port Health Service became increasingly alarmed at the numbers of *A gambiae* found in aircraft arriving from Africa. Despite heavy penalties, the ordinance—which required incoming pilots to keep canopies down and cabin windows closed until the plane had been sprayed by Brazilian staff—was not completely effective, the escape of a single gravid female *A gambiae* to areas beyond the controlled precincts of the airport might well mean disaster for Brazil.

Numbers of *A gambiae* reaching Brazil became so alarming that the Brazilian Government, through both military and diplomatic channels, made representations to the Secretary of State, U S A. As a result, the U S War Department took special action and sent a small expert Commission to investigate the situation. This Commission reported in December 1943, that 'the cause of Brazil's *gambiae* problem lay not so much in neglect of current aircraft spraying regulations as in the neglect of environmental sanitation at West African airfields of departure, where *gambiae* mosquitoes were breeding in large numbers in the immediate vicinity of aircraft parked overnight prior to take-off for

The later history of the 20 patients is shown in a figure, which reveals that 19 of the infections "held their own with scarcely a ripple in the relapse rhythm" which continued unchecked.

Referring to the very large numbers of cases of relapsing *P. vivax* malaria which will be seen in Britain and America for the next few years, and which will be given varied forms of treatment, the authors "trust that the fortune of those who pin their faith on neo-araphenamine will be better than ours"

JANG C. S., FU F. Y. HUANG K. C. & WANG, C. Y. Pharmacology of Ch ang Shan (*Dickroa fefrifuga*) a Chinese Antimalarial Herb. [Correspondence.] *Nature* 1948, Mar 13, 400-401

A number of papers have recently appeared (this *Bulletin*, 1948, v 43 1012 1947 v 44 609 964) dealing with the antimalarial action and chemical nature of the substances present in the herb (*Dickroa fefrifuga*) which has been used in the treatment of malarial fevers in China for centuries. Extracts of the roots (Ch ang Shan) and more especially of the leaves (Shan Chi) have been found by the present authors to be active in *P. gallinaceum* infections of chickens. In all, 5 alkaloids, dichroine α , β and γ (which are quinaroline derivatives) dichroline and quinarolone and two neutral substances, dichrin A (4-hydroxy coumarin) and dichrin B have been obtained from the roots. The first three alkaloids are isomers and are mutually convertible under appropriate conditions. With the probable exception of dichroine α all the isolated substances are stated to possess activity against *P. gallinaceum*. Some chemical and pharmacological properties of the seven substances are given in a table which, however is not very informative. Marked activity in *P. gallinaceum* infections has also been observed in an alkaloidal fraction from another Chinese herb Tou Ch ang Shan (*Hydrangea umbellata*?) which is related to *Dickroa fefrifuga* and from it the authors have succeeded in isolating several alkaloids.

In an added note Dr T. S. Work briefly comments on the chemical aspects of the problem.

HENRY A. P. V. Prémonothérapeutique catalytique du paludisme subaigu et d paludisme chronique (Hémochromatophtérolthérapie) [Catalytic Pre-munition in Subacute and Acute Malaria (Haemochromatophthal Therapy)] *Cahiers Méd. Union Française. Algiers*. 1947 Dec., 2, 3 15 719-25

SHUTE P. G. & MARYON M. The Gametocytocidal Action of Paludrine upon Infections of *Plasmodium falciparum*. *Parasitology* 1948, F b 38, No. 4 284-9

The authors summarize the action of the old anti-malarial drugs on the gametocytes (crescents) of *Plasmodium falciparum* as follows —

| | | |
|---|--|--|
| <i>Quinine</i> Heavy doses 30 grains daily Very small doses | During 1st & 2nd da Later in attack Throughout | Crescent much reduced Crescents scattered Cresc. to numerous |
| <i>Synpharmethal</i> 10 grs. | During 1st day of fever | Cresc. is very numerous |
| <i>M. falciparum</i> Very small dose Larger doses 0.4-0.8 grs. | During 2nd and 3rd days do do 6th or 7th day | Crescent numerous Crescents less numerous Crescents numerous |
| <i>Plasmodium</i> Very small doses | Any time | Crescents sterile |

They then report the results of a number of experiments with paludrine. A patient was infected with the Rumanian strain of *P. falciparum*. The primary attack and the first two relapses [= recrudescences] were lightly treated with paludrine or quinine. The third relapse was allowed to proceed unchecked and it produced a good crop of gametocytes, which readily infected a control batch of mosquitoes—*Anopheles maculipennis* var *atroparvus* (87.5 per cent positive). Paludrine was then given in two divided doses of 0.4 gm each and batches of mosquitoes were fed daily on the patient for 8 days after the administration of the drug and again on the 12th day. Samples of mosquitoes were dissected at appropriate intervals and the results indicated that up to and including the seventh day after paludrine, the mosquitoes failed to become infective—thus confirming Fairley's work at Cairns [this *Bulletin*, 1946, v 43, 527].

Exflagellation of the male crescent occurred normally, and ookinetes were plentiful in all the experiments, and the first indication that paludrine was having an adverse effect, was the small number of oöcysts appearing on the wall of the mid gut. The authors suggest that it is the females upon which the drug acts, without however giving any very satisfactory proof.

[The planning of this experiment is perhaps not quite satisfactory, as the control only refers to the conditions prevailing at the very beginning of the "crescent wave". C. M. Wenyon

LEWERT R. M. Alterations in the Development of *Plasmodium gallinaceum* following Passage through Tissue Culture. *Science* 1948, Mar 5 250

Plasmodium gallinaceum was grown in tissue culture according to the technique of GRY and GRY (*Amer. J. Cancer* 1936, v 27 1) the culture being started either from infected pia mater or from heart muscle. Extensive development did not occur but growth of the parasite continued for as long as 70 days after several subcultures. However the interesting part of this work lies in the results of the inoculation of these cultures into chicks 7-32 days old. The chicks invariably developed an infection of an exclusively exoerythrocytic nature and overwhelming in intensity. No pigmented parasites were ever seen, though in several instances a low percentage of the erythrocytes contained minute uninuclear forms. This peculiar type of infection was maintained unchanged through 9 passages, when intraperitoneal subinoculations of brain emulsions were employed. When blood instead of brain was subinoculated from the same series of chicks, pigmented erythrocytic parasites reappeared by the third passage though even as late as the eighth, the infection continued to be preponderantly exoerythrocytic. It may be noted that by the employment of this technique parasites as young as four days can readily be found in the capillary endothelium of the brain.

BLACKWATER FEVER

LEWIS, P. A. propos d'un cas de fièvre bilieuse hémoglobinoïdique chez un enfant indigène. 'A Case of Blackwater Fever in an African Infant'. *Tr. S. Br. Med. Assoc.* 1917 Sept. 30 & 27, No. 1, 255.

The author describes a case of blackwater fever which occurred during an acute attack of *P. falciparum* malaria in an African child of 23 months in the Belgian Congo. The haemoglobinuria appeared a few hours after an injection of 0.5 gm. of quinine. The patient had had several previous attacks of malaria and was given quinine regularly, but only as a preventative, at frequent but irregular intervals by his father, at the medical advice to the contrary.

After the attack of blackwater fever had been cured by local measures and the existing *P. falciparum* infection had been treated with meprazine, the patient five days later developed another acute attack of malaria with *P. falciparum* in his blood. He suffered four more such attacks within the following year. Because of the frequent danger of blackwater fever in a susceptible subject it was decided to try the effect of meprazine prophylaxis. The last attack was treated like the preceding ones with 0.1 gm. of meprazine daily for 5 days, followed by 0.01 gm. of plasmogone daily for 5 days, after which 0.1 gm. of meprazine was given under direct medical or nursing supervision every Monday and Thursday. No more malarial attacks have occurred, the blood has remained negative on five examinations, and the spleen is not palpable. The child attends the dispensary regularly, twice a week for meprazine prophylaxis and is in excellent health at the present age of 3 years and nine months. The author returns the danger of irregular quinine prophylaxis in Africans and the indiscriminate use of the drug without medical control.

The rarity of blackwater fever in Africans, owing to the 'premunition' established is well recognized. It is suggested that this exceptional case occurred because the patient's circumstances regarding frequent malarial attacks and the irregular taking of quinine were the same as those commonly encountered among Europeans who develop blackwater fever. *H. LEWIS, H. Haemolytic System in the Blood of Malaria-Infected Monkeys Correspondence. *Nature* 1918 Apr. 10, 560.

This is a preliminary report, details of which will appear elsewhere, of a haemolytic substance found in heavily parasitized (*Plasmodium knowlesi*) monkey blood. The parasites seem to produce it or cause its appearance in the erythrocytes, which it destroys when its concentration is high. It is then released into the plasma. It does not appear to differ (except in its higher quantity) from a haemolytic substance obtained from normal blood and other tissues, and previously reported by the author and Burrows (*Nature*, 1915, Oct. 27, 507). It has so far been characterized as an unsaturated monocarboxylic fatty acid having one double bond and the possible chain length C18. Its haemolytic activity is inhibited specifically by intestinal drugs.

The mechanism may be thought of as enabling the metabolic utilization of the red cell by the parasite. Malaria pigment, which is a haematin compound, accentuates this mode of erythrocytic destruction by the parasite. Haematin has itself been found to be haemolytic *in vitro* in low concentrations and in sub-haemolytic concentrations it strongly potentiates the effect of the haemolytic substance now described.

The author notes that it might be interesting to study the quantitative relations of these two factors in the blood of persons suffering from blackwater fever.

TRYPANOSOMIASIS

LOURENÇO MARQUES. Conferência Intercolonial sobre Tripanosomíase, Lourenço Marques, 28 a 31 de Agosto de 1946. [Inter-Colonial Conference on Trypanosomiasis, Lourenço-Marques, 1946.] Vol. I 387 pp. Vol. II 458 pp. Numerous figs., maps & charts. 1947 Lourenço Marques Imprensa Nacional do Moçambique.

It is evident that the Conference which took place in Portuguese East Africa on trypanosomiasis in 1946 was important. It was attended by delegates from almost all parts of British and Portuguese Africa, in which tsetse occurs and among them there were men interested in human and animal medicine, entomology agriculture and administration.

The report of the Conference is in English and Portuguese, and every word, including small parts of the discussion, is set down in both languages. The report has, therefore, a tendency to be diffuse and it is not easy to extract the conclusions or to find which parts of it are of permanent value. Certain topics which were discussed more than once appear in several different places the table of contents is so brief that it does not give one much help.

Where Portuguese originals have been translated into English the language is generally good and clear. A few technical errors have been noted, for instance "ape" for "baboon" "locks" for "locks" and "oxen plague" for "rinder pest". The phrase "typical podagral lesions were found in cudos" is presumed to mean that foot lesions, characteristic of foot and mouth disease, were found in kudus.

The report is illustrated with numerous maps, many of them in colours and with half tone blocks of the delegates sitting at the conference. The general presentation of the report reflects great credit on the Government printer at Lourenço Marques.

The volumes contain valuable information on several sides of the subject which had previously been obscure. The coloured maps give the distribution of Gloss as a whole and of some of the species, also distribution of trypanosomiasis of man and animals. Some of them deal with parts of the world such as Angola, Swaziland and Portuguese East Africa, about which it has been difficult to get up-to-date information. We note also a report by HONNEY on the present distribution of *G. morsitans* along the Save River and on the possible danger of its extension to the lower part of the valley of the Limpopo.

There are two valuable contributions from CHOMLEY of Southern Rhodesia. In the first he deals with the history of the distribution of *G. morsitans* and nagana in that territory much of his facts being gathered from the records of hunters and travellers about seventy to ninety years ago. It is evident that fly was driven back, probably because hunters and the great epidemic rinder pest in 1893 killed the game. The fly then commenced to re-occupy much territory. The second paper gives a general account of the measures, principally game exclusion and game destruction, which were undertaken to drive *G. morsitans* back again. This is a very important piece of work for Southern Rhodesia has recovered a much larger area from fly than has any other African territory. The present paper is the only general account of what has been done, and we feel that the matter deserves more than the three pages given to it. We understand that the cost of the operation was remarkably low but so that no information is given.

South African authors gave the conference an account of the use of DDT in mineral oil sprayed from the air against *C. papalis* in a small game area in Zululand. The paper by DE TOIT gives most useful information on the practical measures undertaken, e.g. organization, spray formula, dosage cost and the effect on the tsetse as measured by traps.

It is evident that the clinicians had a varied and stimulating day. SOUSA first discussed what criteria should be used in estimating a cure of Gambian sleeping sickness, RAMOS and ASSOREIRA passed on to consider blindness in this infection. It is attributable to 'trypanosomic opto-chiasmatic arachnoiditis'. This condition is apparently to be treated by intracarotid injections of trypanamide, pericardial sympathectomy, or even frontal craniotomy to eliminate adhesions in the opto-chiasmatic region. Penicillin when administered by the intravenous or intramuscular route is without effect on trypanosomiasis. If it is given intrathecally, the trypanosomes disappear temporarily from the cerebrospinal fluid but the course of the disease is not affected.
